Abstract

A new approach for studying wave propagation phenomena in an inviscid gas is presented. This approach can be viewed as the extension of the method of characteristics to the general case of unsteady multidimensional flow. The general case of the unsteady compressible Euler equations in several space dimensions is examined. A family of spacetime manifolds is found on which an equivalent one-dimensional problem holds. Their geometry depends on the spatial gradients of the flow, and they provide, locally, a convenient system of coordinate surfaces for spacetime. In the case of zero entropy gradients, functions analogous to the Riemann invariants of 1-D gas dynamics can be introduced. These generalized Riemann Invariants are constant on these manifolds and, thus, the manifolds are dubbed Riemann Invariant Manifolds (RIM). In this special case of zero entropy gradients, the equations of motion are integrable on these manifolds, and the problem of computing the solution becomes that of determining the manifold geometry in spacetime. This situation is completely analogous to the traditional method of characteristics in one-dimensional flow.

† Professor of Aeronautics.

‡ Professor of Aeronautics and Applied Physics.

Explicit expressions for the local differential geometry of these manifolds can be found directly from the equations of motion. The local direction and speed of propagation of the waves that these manifolds represent, can be found as a function of the local spatial gradients of the flow. Their geometry is examined, and in particular, their relation to the characteristic surfaces. It turns out that they can be space-like or time-like, depending on the flow gradients. Wave propagation can be viewed as a superposition of these Riemann Invariant waves, whenever appropriate conditions of smoothness are met. This provides a means for decomposing the equations into a set of convective scalar fields in a way which is different and potentially more useful than the characteristic decomposition. The two decompositions become identical in the special case of one-dimensional flow. This different approach can be used for computational purposes by discretizing the equivalent set of scalar equations. Such a computational application of this theory leads to the possibility of determining the solution at points in spacetime using information that propagates faster than the local characteristic speed, *i.e.*, using information outside the domain of dependence. This possibility and its relation to the uniqueness theorems is discussed.

1. Introduction

A great deal of work has contributed to the understanding of nonlinear hyperbolic systems of equations, such as the compressible Euler equations. The main ingredient in the study of such systems is the concept of characteristic surfaces and the theory describing their properties. See, for example, Courant and Hilbert (1963). A brief summary of the theory is given in the appendix.

Characteristic surfaces in spacetime can be viewed as propagating wave fronts and are usually interpreted as disturbance waves in the system that the equations represent. This picture becomes more useful and much clearer in the special case of systems in two independent variables, where one of the independent variables is time. It is in this special case that most of the work has been done. It is useful to think about unsteady one-dimensional gas dynamics as an example of this case. The characteristic surfaces now become curves in two-dimensional spacetime. This is a serious simplification, since now there are only two possible propagation directions for waves, the positive and negative spatial direction. Moreover, the equations written along these characteristic directions are greatly simplified. Under certain conditions, one can define functions that are invariant along these paths. They are the familiar Riemann Invariants. The solution can be written, locally, in spacetime as a superposition of these characteristic waves. Each invariant satisfies a simple convective equation, thus, the original system of equations is replaced by an equivalent set of convective scalar equations. This is the decomposition into the characteristic scalar fields. For gas dynamics one has convective waves that propagate with the local fluid velocity and the acoustic waves that propagate with the local speed of sound, in the reference frame of the fluid.

When there are more than two independent variables, such as the case of unsteady multidimensional flow in a gas, the situation becomes more difficult. The characteristic curves now become characteristic manifolds in a higher dimensional spacetime. These manifolds can be viewed as being generated, locally, by appropriate vector fields. The directions of these vector fields are dubbed *bicharacteristic* directions and the vector fields are generators of a cone which is called the *bichar-*

acteristic cone. This cone is tangent to the characteristic manifolds. Now, there are more than just two available directions for the propagation of waves. This difficulty is to be expected, but in addition to this, the equations no longer simplify the same way as in one-dimensional flow. The equations can be written along the bicharacteristic directions and the characteristic decomposition of the original system into scalar fields can be carried out, formally, as in the case of two independent variables. But now, the equations are not simpler in any way than the original system. Riemann Invariants no longer exist along these paths and the solution cannot be written as a simple superposition of waves as before.

These difficulties in higher dimensional systems become more important in light of possible numerical applications and use of these ideas to create accurate computational methods for generating solutions. The basic theory of characteristics for 1-D flows in gas dynamics was used in the past as a computational tool under the name *Method of Characteristics*. Under the assumption of zero entropy gradients the equations are integrable along the characteristics and so the problem of computing the solution is equivalent to the problem of numerically generating the characteristic paths in two-dimensional spacetime. The extension of the method to multidimensional flows runs into difficulties for the reasons mentioned above. A good attempt at extending it is given by Butler (1960), who also discusses the difficulties.

In the present paper a different type of local wave decomposition, the RIM decomposition, is given for the compressible Euler equations, which holds under slightly different smoothness assumptions than the familiar characteristic decomposition. Manifolds in spacetime are found on which there are Riemann Invariants analogous to those in 1-D flow. If N is the number of spatial dimensions, there is, in general, an $(N - 1)$ -parameter family of such N -dimensional manifolds in spacetime on which these generalized Riemann Invariants are constant. For paths along these manifolds the equations of motion reduce to the equations of 1-D flow. By projecting the equations of motion on these hypersurfaces, as a first step, one can integrate them numerically or otherwise by using techniques that work with

1-D problems. Of course this projection requires care. Generalized Riemann Invariants exist as long as there are no entropy gradients. The situation is completely analogous to the one-dimensional case. Explicit expressions for the direction and speed of propagation of the wave fronts that these manifolds represent are found directly from the Euler equations. It turns out that they depend on particular combinations of the spatial pressure and velocity gradients. The ability to write explicit expressions for these waves is what makes this decomposition very useful from a theoretical and computational point of view. Knowledge of the spatial gradients in the flow contains a great deal more information, locally, than that given by the familiar characteristic decomposition. Moreover, the combinations of spatial gradients that are important are revealed in a very natural way by seeking paths along which the one-dimensional equations hold. It is these combinations that pick out important directions of local wave propagation. Moreover, it becomes apparent that it is possible in some cases to compute the solution at a certain point in space-time using information from outside its domain of dependence. This is because the appropriate Riemann Invariant waves may be traveling at speeds greater than the largest characteristic speed. Also, it is possible for a subsonic flow to exhibit, locally, a “hyperbolic”-type behavior depending on the flow gradients. This result is interesting and its relation to the theorems of uniqueness is discussed. Details on the proofs of these uniqueness theorems can be found in Courant and Hilbert (1963); Friedrichs (1954); Friedrichs and Lax (1965), and Kato (1975).

The proposed RIM wave decomposition is also useful in the context of the recent high-resolution schemes developed for computing hyperbolic systems of equations such as the compressible Euler equations. These high-resolution schemes, such as the ENO and TVD schemes, described by Harten *et al.* (1987) and Harten (1983,1984), the MUSCL scheme introduced by van Leer (1979), PPM by Colella and Woodward (1984) and Roe’s Approximate Riemann Solver given by Roe (1981), take advantage of the extensive theory on hyperbolic systems of equations in two independent variables. The main idea is to develop stable and at least second-order accurate schemes for computing a scalar convective equation. Systems of equations are then treated by using the characteristic decomposition into scalar fields, which

works very well for systems in just two independent variables. Weak solutions, *i.e.*, discontinuous solutions are allowed by using a conservative formulation and making sure that the discretization of the scalar field equations is at least second-order accurate, but does not generate spurious oscillations. In the context of gas dynamics the above procedure can be viewed as using, locally at each computational cell interface, the method of characteristics to compute the appropriate flux terms. Since discontinuous solutions are expected, the method is generalized by solving an appropriate Riemann problem. The solution to this Riemann problem has to reduce to a second-order solution to the characteristic scalar field equations in the absence of discontinuities. This is the spirit of extending to second-order accuracy the original Godunov scheme (1959).

Although the application of this idea is straightforward for the one-dimensional case, the extension to multidimensional flows is not. Practically, these schemes are extended to more dimensions by treating the additional spatial dimensions separately. The computation is not truly multidimensional, but rather a number of separate, one-dimensional computations in each spatial direction. Even schemes that appear to be multidimensional (unsplit), actually use the local directions of the grid to set up and solve a 1-D Riemann problem, thus taking advantage of the 1-D results. Efforts to create a genuinely multidimensional scheme are those by Roe (1986); Hirsch & Lacor (1989), and Deconinck *et al.* (1986). A true extension of the Godunov scheme to the multidimensional case would be finding a solution to the multidimensional Riemann problem. For 1-D gas dynamics, it can be shown that the Riemann problem has a unique solution and that the general, initial value problem has a unique weak solution. See Glimm (1965) and Smoller (1983). This has not yet been done in higher dimensions. The wave decomposition presented in this paper can help in generating unsplit schemes for computing gas dynamical flows. It provides a way of using the 1-D techniques in a mathematically consistent way. When the equations are “projected” on the Riemann Invariant Manifolds they become the 1-D equations. A different way of looking at it is, that this new wave decomposition provides one with a set of convective scalar field equations that can be discretized in the spirit of the high-resolution schemes such as TVD. Moreover,

this decomposition reduces exactly to the characteristic one in 1-D flow.

2. The Compressible Euler Equations

2.1 Characteristic theory

The equations of interest are those governing the 3-D inviscid flow of a compressible fluid. All the results presented hold for the general three-dimensional case, although for visualization purposes the figures are given for 2-D flow. It is much easier to visualize a three-dimensional spacetime than a four-dimensional one. The equations of motion can be written in the non-conservative form

$$\begin{aligned}\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) &= 0 \\ \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} + \frac{1}{\rho} \nabla p &= 0 \\ \frac{\partial p}{\partial t} + \mathbf{u} \cdot \nabla p + \rho a^2 \nabla \cdot \mathbf{u} &= 0,\end{aligned}\tag{1}$$

where ρ is the density, p is the pressure, $\mathbf{u} = (u, v, w)^T$ is the velocity vector and a is the speed of sound. Eqs. (1) can be written in the general form

$$\frac{\partial U}{\partial t} + A_x \frac{\partial U}{\partial x} + A_y \frac{\partial U}{\partial y} + A_z \frac{\partial U}{\partial z} = 0,\tag{2}$$

where

$$\begin{aligned}U &= \begin{pmatrix} \rho \\ u \\ v \\ w \\ p \end{pmatrix}, & A_x &= \begin{pmatrix} u & \rho & 0 & 0 & 0 \\ 0 & u & 0 & 0 & 1/\rho \\ 0 & 0 & u & 0 & 0 \\ 0 & 0 & 0 & u & 0 \\ 0 & \rho a^2 & 0 & 0 & u \end{pmatrix}, \\ A_y &= \begin{pmatrix} v & 0 & \rho & 0 & 0 \\ 0 & v & 0 & 0 & 0 \\ 0 & 0 & v & 0 & 1/\rho \\ 0 & 0 & 0 & v & 0 \\ 0 & 0 & \rho a^2 & 0 & v \end{pmatrix}, & A_z &= \begin{pmatrix} w & 0 & 0 & \rho & 0 \\ 0 & w & 0 & 0 & 0 \\ 0 & 0 & w & 0 & 0 \\ 0 & 0 & 0 & w & 1/\rho \\ 0 & 0 & 0 & \rho a^2 & w \end{pmatrix}.\end{aligned}\tag{3}$$

There are five unknown functions defined on 4-dimensional spacetime, *i.e.*, $N = 3$ spatial dimensions. One can easily specialize the following results to the case $N = 2$, or $N = 1$. This is a hyperbolic system and its characteristic manifolds can be found in a straightforward way. There is a convective characteristic surface which is locally generated by the fluid velocity \mathbf{u} and a family of acoustic characteristic surfaces that are generated by the local bicharacteristic vectors $\mathbf{u} + a\mathbf{n}$, where \mathbf{n} is a spatial unit vector. Details can be found in the appendix.

The differential equations that hold on the characteristic manifolds can be found, formally, by attempting to diagonalize the matrices that appear in Eq. (2). Given an arbitrary unit vector \mathbf{n} , a straightforward calculation yields the left and right eigenvectors of the matrix $\mathbf{n} \cdot \mathbf{A}$, where $\mathbf{A} = (A_x, A_y, A_z)^T$. The differential equation that holds along a characteristic ray can be found by multiplying from the left by the appropriate eigenvector; *i.e.*,

$$\left\langle l_k, \frac{\partial U}{\partial t} \right\rangle + \left\langle l_k, A_m \frac{\partial U}{\partial x_m} \right\rangle = 0, \quad k = 1, \dots, M, \quad (4)$$

where $\langle \cdot, \cdot \rangle$ is the usual inner product in \mathbb{R}^M and M is the number of equations, *i.e.*, $M = 5$. The summation convention is adopted for all repeated indices. By multiplying from the left with the left eigenvectors l_k corresponding to the acoustic manifold of the Euler equations, one finds the differential equation, which holds along the bicharacteristic, $\dot{\mathbf{x}}(t) = \mathbf{u} + a\mathbf{n}$,

$$\begin{aligned} \left[\frac{\partial p}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla p \right] + \rho a \mathbf{n} \cdot \left[\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla \mathbf{u} \right] \\ + \rho a^2 [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}] = 0. \end{aligned} \quad (5)$$

Using index notation and dividing through by ρa ,

$$\begin{aligned} \frac{1}{\rho a} \left[\frac{\partial p}{\partial t} + (u_j + a n_j) \frac{\partial p}{\partial x_j} \right] + n_i \left[\frac{\partial u_i}{\partial t} + (u_j + a n_j) \frac{\partial u_i}{\partial x_j} \right] \\ + a (\delta_{ij} - n_i n_j) \left(\frac{\partial u_i}{\partial x_j} \right) = 0, \end{aligned} \quad (6)$$

where δ_{ij} is the Kronecker delta. Since the tensor $\delta_{ij} - n_i n_j$ is symmetric,

$$G_n \equiv (\delta_{ij} - n_i n_j) \left(\frac{\partial u_i}{\partial x_j} \right) = (\delta_{ij} - n_i n_j) S_{ij}, \quad (7)$$

where

$$S_{ij} \equiv \frac{1}{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right)$$

is the rate of strain tensor. Only the symmetric part of the velocity-gradient tensor enters in the term G_n .

The significance of Eq. (5) can be seen by deriving it in a way that is not related to the concept of characteristic manifolds. Consider an arbitrary, spatial, unit vector \mathbf{n} . The last two equations in (1) can be combined to give Eq. (5). The momentum equation can be written as follows, by taking its inner product with the vector $\rho a \mathbf{n}$ and adding and subtracting the term $\rho a^2 \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}$; i.e.,

$$\begin{aligned} \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} + \frac{1}{\rho} \nabla p &= 0 \\ \Rightarrow \quad \rho a \mathbf{n} \cdot \left[\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} + a \mathbf{n}) \cdot \nabla \mathbf{u} \right] - \rho a^2 \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n} + a \mathbf{n} \cdot \nabla p &= 0. \end{aligned}$$

The energy equation can be written

$$\begin{aligned} \frac{\partial p}{\partial t} + \mathbf{u} \cdot \nabla p + \rho a^2 \nabla \cdot \mathbf{u} &= 0 \\ \Rightarrow \quad \frac{\partial p}{\partial t} + (\mathbf{u} + a \mathbf{n}) \cdot \nabla p + \rho a^2 \nabla \cdot \mathbf{u} - a \mathbf{n} \cdot \nabla p &= 0. \end{aligned}$$

Adding the two equations gives Eq. (5).

It is clear from this derivation that this equation holds for an arbitrary vector \mathbf{n} . It gives the relation between velocity changes and pressure changes along the direction $\dot{\mathbf{x}} = \mathbf{u} + a \mathbf{n}$. It is our knowledge of the characteristic surfaces, which allows us to identify these directions as the generating rays of the acoustic characteristic manifold, i.e., the bicharacteristics. It is also important to notice that it is really a family of equations. By fixing \mathbf{n} to be a unit vector, it is easy to see that Eq. (5) or (6) is actually an $(N - 1)$ -parameter family of equations. Indeed, for two-dimensional flow ($N = 2$), the vector \mathbf{n} is constrained to the unit circle and for three-dimensional flow it is constrained to the surface of the unit sphere. This is important because, although they are all dependent equations and consistent with the original system (1), a particular choice of \mathbf{n} may be optimal for computational purposes.

If there are no entropy gradients, then (5) can be further simplified. Define the thermodynamic state variable W by

$$W \equiv \int_{ds=0} \frac{dp}{\rho a}, \quad (8)$$

where the integral is performed in thermodynamic state space along a path of constant entropy s . For a perfect gas this function is simply

$$W = \frac{2a}{\gamma - 1}, \quad (9)$$

where γ is the specific heat ratio. Then, Eq. (5) can be written

$$\begin{aligned} \left[\frac{\partial W}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla W \right] + \left[\frac{\partial(\mathbf{u} \cdot \mathbf{n})}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla(\mathbf{u} \cdot \mathbf{n}) \right] \\ + a [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}] = 0. \end{aligned} \quad (10)$$

The vector \mathbf{n} is assumed to be constant. One can define a family of functions given by

$$R_n \equiv W + \mathbf{u} \cdot \mathbf{n}. \quad (11)$$

These functions are going to be the generalization of the familiar Riemann Invariants of one-dimensional flow. Eq. (10) can now be written

$$\frac{\partial R_n}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla R_n + a [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}] = 0, \quad (12a)$$

or

$$\frac{\partial R_n}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla R_n + aG_n = 0. \quad (12b)$$

The presence of the term $aG_n = a(\delta_{ij} - n_i n_j) S_{ij}$ in Eq. (12) acts as a source term and complicates matters in multidimensional flows. If a unit vector \mathbf{n} exists, such that $G_n = 0$, then along the direction $\dot{\mathbf{x}} = \mathbf{u} + a\mathbf{n}$, Eq. (12) is integrable and $R_n = \text{const}$. By examining the form of G_n , one can see that it is not always possible to find such a direction \mathbf{n} . G_n is the two-dimensional divergence of the velocity field in the plane normal to the vector \mathbf{n} . For the case of 2-D flow, *i.e.*, $N = 2$, it can be shown that a direction \mathbf{n} , such that $G_n = 0$, can be found only when the eigenvalues of the rate of strain tensor S are such that

$$\lambda_{\min} \lambda_{\max} \leq 0. \quad (13)$$

This condition is not always satisfied in an arbitrary flow.

One can find the equations that hold along the convective characteristic manifolds in a similar way. After this is done, it can be seen that the original Euler equations are equivalent to the following characteristic system of equations,

$$\begin{aligned}\frac{\partial R_n}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla R_n &= -aG_n \\ \frac{\partial R_0}{\partial t} + \mathbf{u} \cdot \nabla R_0 &= 0,\end{aligned}\tag{14}$$

where

$$G_n = [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}] = (\delta_{ij} - n_i n_j) S_{ij}.$$

The invariant R_0 along the convective manifold can be viewed as the entropy of the system, which is constant along a streamline in the absence of shocks. Eqs. (14) constitute the characteristic decomposition of the Euler equations into scalar fields.

Consider now the special case of one-dimensional flow ($N = 1$) in the x -direction. The characteristic surfaces are now characteristic curves in two dimensional spacetime (t, x) , given by

$$C_{\pm} : \frac{dx}{dt} = u \pm a.\tag{15}$$

The only possible choices for the unit vector are $\mathbf{n} = \pm \hat{e}_x$, where \hat{e}_x is the unit vector in the direction of the flow. The family of Equations (5) consists of just the two equations in the direction of the two characteristics,

$$\frac{1}{\rho a} \left[\frac{\partial p}{\partial t} + (u \pm a) \frac{\partial p}{\partial x} \right] \pm \left[\frac{\partial u}{\partial t} + (u \pm a) \frac{\partial u}{\partial x} \right] = 0.\tag{16}$$

These two equations are written in the more conventional form as

$$\frac{1}{\rho a} \frac{dp}{dt} \pm \frac{du}{dt} = 0,\tag{17}$$

where the time derivatives are derivatives along the appropriate characteristic directions. The equations are greatly simplified because the source-like term G_n is identically zero. When there are no entropy gradients in the flow, Eqs. (14) reduce to

$$\begin{aligned}\frac{\partial R_{\pm}}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla R_{\pm} &= 0 \\ \frac{\partial R_0}{\partial t} + \mathbf{u} \cdot \nabla R_0 &= 0.\end{aligned}\tag{18}$$

The two functions R_{\pm} are the familiar Riemann Invariants and are indeed invariant along the characteristic directions as shown in (18). It is in this special one-dimensional case that the characteristic decomposition is computationally useful and also gives a clear picture of wave propagation as a local superposition of characteristic waves. Eqs. (18) are the starting point for the method of characteristics. Indeed, they can be integrated to give

$$\frac{d}{dt}(W \pm u) = 0 \Rightarrow R_{\pm} \equiv W \pm u = \text{const}, \quad (19)$$

along the characteristic directions. The problem of integrating the Euler equations reduces to a geometric one in spacetime; that of integrating the characteristic curves.

Looking at the general multidimensional decomposition (14), there is no apparent advantage in integrating the equations of motion along the bicharacteristic directions, which can be viewed as the multidimensional extensions of the characteristics in 1-D. First, one has a multitude of bicharacteristic directions to choose from and second, the equations of motion do not greatly simplify because of the presence of the source-like term G_n . The generalization of the simple, one-dimensional results does not appear to be straightforward, and this has thwarted many efforts to extend the method of characteristics to higher dimensions. The characteristic surfaces are significant for theoretical reasons and primarily for the role they play in proving the existence and uniqueness of solutions. The existence and uniqueness theorems are closely related to the concepts of domain of dependence and domain of influence. Integrating along paths on the characteristic surfaces gives no advantage over integrating along, say, $x = \text{const}$ paths, which is what is usually done on a computer.

2.2 Riemann Invariant Manifolds

A different type of wave decomposition occurs when one asks the question:

is it possible to find paths in spacetime along which $R_n = \text{const}$?

These paths would be similar to the characteristics in 1-D and could be used as integrating paths. Obviously, these paths are not the bicharacteristics. The paths of interest will have to lie on the surfaces $R_n(t, \mathbf{x}) = \text{const.}$ These surfaces can be viewed as Riemann Invariant waves and can be used to construct solutions, numerically. They are given the name Riemann Invariant Manifolds (RIM). At first sight, it is not clear why looking for invariants will be useful or whether it is possible to find explicit expressions for their speed and direction of propagation directly from the equations of motion. These matters will be clarified in the end. For now let's find such paths in spacetime, motivated solely by the one-dimensional implementation of the method of characteristics.

It is easy to see what paths lie on the surfaces $R_n = \text{const}$ in spacetime by adding and subtracting the following term in Eq. (12),

$$\mathbf{v} \cdot \nabla R_n , \quad (20)$$

where \mathbf{v} is a velocity. Eq. (12) is now written

$$\frac{\partial R_n}{\partial t} + (\mathbf{u} + a\mathbf{n} + \mathbf{v}) \cdot \nabla R_n + aG_n - \mathbf{v} \cdot \nabla R_n = 0 . \quad (21)$$

If the velocity \mathbf{v} is chosen so that

$$\mathbf{v} \cdot \nabla R_n = aG_n = a[\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}] , \quad (22)$$

then

$$\frac{\partial R_n}{\partial t} + (\mathbf{u} + a\mathbf{n} + \mathbf{v}) \cdot \nabla R_n = 0 . \quad (23)$$

Eq. (23) says that along the paths

$$\dot{\mathbf{x}}(t) = \mathbf{V} \equiv \mathbf{u} + a\mathbf{n} + \mathbf{v} , \quad (24)$$

the function R_n is constant. Eq. (22) is simply a compatibility condition, which must be satisfied by the integral curve of (24), in order for it to lie on the surface $R_n = \text{const.}$ The velocity \mathbf{v} depends on the local, spatial gradients of the flow, as can be seen from Eq. (22). Given a point in the flow where ∇R_n and G_n have a

specified value, this relation is linear in the velocity components of \mathbf{v} . The reason is that there is an infinity of curves passing through this given point, which lie on the surface $R_n = \text{const}$. See Fig. 1. All possible choices of \mathbf{v} correspond to all possible directions of motion on this surface. Moreover, it is well known from differential geometry that there are an infinity of curves for every such direction. In what follows, some interesting and useful choices of directions will be examined.

FIG.1 The surface $R_n(t, \mathbf{x}) = \text{const}$ in three-dimensional spacetime. There are an infinity of curves passing through a given point, which lie on this surface.

The assumption of zero entropy gradients allowed the introduction of the Riemann Invariants R_n , which simplified the analysis by making the equations integrable. Let's abandon this assumption and repeat the previous analysis. Eq. (5) will be the starting point:

$$\left[\frac{\partial p}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla p \right] + \rho a \mathbf{n} \cdot \left[\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla \mathbf{u} \right] + \rho a^2 [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}] = 0.$$

By adding and subtracting the term

$$\mathbf{v} \cdot [\nabla p + \rho a \nabla(\mathbf{u} \cdot \mathbf{n})] = \mathbf{v} \cdot [\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}], \quad (25)$$

and for a \mathbf{v} chosen so that

$$\mathbf{v} \cdot [\nabla p + \rho a \nabla(\mathbf{u} \cdot \mathbf{n})] = \rho a^2 [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}] , \quad (26)$$

one finds

$$\left[\frac{\partial p}{\partial t} + (\mathbf{u} + a\mathbf{n} + \mathbf{v}) \cdot \nabla p \right] + \rho a \left[\frac{\partial(\mathbf{u} \cdot \mathbf{n})}{\partial t} + (\mathbf{u} + a\mathbf{n} + \mathbf{v}) \cdot \nabla(\mathbf{u} \cdot \mathbf{n}) \right] = 0 . \quad (27)$$

Again \mathbf{n} is assumed to be a constant vector. Eq. (27) can be written in a more conventional form as

$$\frac{1}{\rho a} \frac{dp}{dt} + \frac{du_n}{dt} = 0 , \quad (28)$$

along the paths

$$\dot{\mathbf{x}}(t) = \mathbf{V} \equiv \mathbf{u} + a\mathbf{n} + \mathbf{v} , \quad (29)$$

where $u_n \equiv \mathbf{u} \cdot \mathbf{n}$, i.e., the velocity component in the direction of the fixed \mathbf{n} vector. Eq. (28) is of the same form as the first of Eqs. (17), which holds along the C_+ characteristic in the 1-D case. The previous discussion for the $R_n = \text{const}$ surfaces holds for these manifolds as well, but their interpretation is different and more general. The solutions at any two points on such a manifold, connected by a trajectory given by (29), are related in exactly the same way that solutions are related along characteristics in the 1-D case. Knowledge of the integral curves of the vector field (29) allows one to use the simple results of the one-dimensional theory in multidimensional flows. In what follows, the notation $R_n = \text{const}$ will be used for these manifolds even when entropy gradients are present and the Riemann Invariants $R_n = W + \mathbf{u} \cdot \mathbf{n}$ cannot be used.

2.3 Geometry of the Riemann Invariant Manifolds

It is interesting to see what the geometry of these manifolds is, especially in relation to the characteristic manifolds. A few different ways of describing their geometry are presented in what follows.

One way of visualizing the relative position of the characteristic manifolds and the Riemann Invariant Manifolds is by examining the motion of the equivalent $(N - 1)$ -dimensional fronts. Recall that any surface $\varphi(t, \mathbf{x}) = 0$ in spacetime, is equivalent to a wave front. For simplicity consider the case of a two-dimensional flow; *i.e.*, $N = 2$. Fig. 2, shows the local geometry and motion of the wave front $R_n = \text{const}$ for a finite time Δt . The local unit normal of this front is

$$\mathbf{N} = \frac{\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}}{|\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}|}. \quad (30)$$

For the case of zero-entropy gradients, this is seen to be

$$\mathbf{N} = \frac{\nabla R_n}{|\nabla R_n|}. \quad (31)$$

It is important to note that the unit normal \mathbf{n} serves as a label for the particular manifold. It determines the fluid velocity component that is used for the equivalent, one-dimensional problem. The vector \mathbf{n} should be considered as the parameter of the one-parameter family of Riemann Invariant wave fronts. From Eq. (30), it is apparent that \mathbf{N} depends on \mathbf{n} . Moreover, the mapping is not bijective; *i.e.*, it is not always possible to find a wave front $R_n = \text{const}$ for an arbitrary \mathbf{N} . The spatial gradients of the flow determine a range of allowed propagation directions \mathbf{N} for these fronts. This is very important, because it is the reason why even a subsonic flow may exhibit locally a "hyperbolic"-type behavior.

It is also useful to define the vector \mathbf{n}^- , which determines the front propagating in the $-\mathbf{N}$ direction; *i.e.*,

$$-\mathbf{N} = \frac{\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}^-}{|\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}^-|}, \quad (32)$$

if it exists. One can also define \mathbf{N}^- by

$$\mathbf{N}^- = \frac{\nabla p - \rho a (\nabla \mathbf{u})^T \mathbf{n}}{|\nabla p - \rho a (\nabla \mathbf{u})^T \mathbf{n}|}. \quad (33)$$

FIG.2 Local geometry of the Riemann Invariant front $R_n = \text{const}$. The outer normal is \mathbf{N} and its velocity is \mathbf{V} .

It is important to keep in mind that in general, $\mathbf{n}^- \neq -\mathbf{n}$ and $\mathbf{N}^- \neq -\mathbf{N}$.

The velocity of the front $R_n = \text{const}$ is given by

$$\mathbf{V} = \mathbf{u} + a\mathbf{n} + \mathbf{v}, \quad (34)$$

where \mathbf{v} has to satisfy Eq. (26); i.e.,

$$\mathbf{v} \cdot [\nabla p + \rho a \nabla(\mathbf{u} \cdot \mathbf{n})] = \rho a^2 [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}]. \quad (35)$$

The geometry of the front at time $t + \Delta t$ is completely determined by the normal front velocity. One can add an arbitrary, tangential velocity component without changing the front geometry. This freedom is seen in choosing the velocity component \mathbf{v} , which need only satisfy Eq. (35). This equation represents a straight line in velocity space. It is possible to find the front velocity that corresponds to minimum $|\mathbf{v}|$. This is the case when $\mathbf{v} \parallel \mathbf{N}$. The corresponding front velocity is

$$\mathbf{V}_H = \mathbf{u} + a\mathbf{n} + \frac{\rho a^2 [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}]}{|\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}|} \mathbf{N}. \quad (36)$$

The integral curves of this vector field are the curves on the manifold $R_n = \text{const}$, which are closest to the bicharacteristics $\dot{\mathbf{x}}(t) = \mathbf{u} + a\mathbf{n}$. The normal front velocity can be found by combining Eqs. (30), (34) and (35),

$$\mathbf{V}_N \equiv (\mathbf{V} \cdot \mathbf{N})\mathbf{N} = (\mathbf{u} \cdot \mathbf{N})\mathbf{N} + \mathcal{M}_n a \mathbf{N}, \quad (37)$$

where \mathcal{M}_n is a dimensionless number defined by

$$\mathcal{M}_n \equiv \frac{\mathbf{n} \cdot \nabla p + \rho a \nabla \cdot \mathbf{u}}{|\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}|}, \quad (38)$$

and plays the role of an algebraic Mach number. The front velocity can also be chosen so that the integral curve of this vector field is as close to the fluid streamline as possible. This is done by minimizing $|a\mathbf{n} + \mathbf{v}|$ in Eq. (34). It is possible to show that this is minimized when $(a\mathbf{n} + \mathbf{v}) \parallel \mathbf{N}$. The front velocity in this case is given by

$$\mathbf{V}_S = \mathbf{u} + \mathcal{M}_n a \mathbf{N}. \quad (39)$$

This particular choice of front velocity is very useful because it resembles the bicharacteristic velocities that generate the characteristic manifolds. It is clear that the parameter \mathcal{M}_n is an indication of how much the manifold $R_n = \text{const}$ deviates from the local characteristic surfaces. In Fig. 3, a normal slice of these surfaces is shown. A normal slice is the intersection of the surface with the plane defined by the direction \mathbf{N} and the time axis. The surface $R_n = \text{const}$ is characteristic when $\mathcal{M}_n = \pm 1$. Furthermore, it is time-like when $-1 < \mathcal{M}_n < 1$ and space-like when $|\mathcal{M}_n| > 1$. The following useful relation can be found by combining Eqs. (30), (35) and (38),

$$\mathcal{M}_n = \mathbf{n} \cdot \mathbf{N} + \frac{\rho a G_n}{|\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}|}. \quad (40)$$

Most of the geometrical information of the Riemann Invariant Manifolds is contained in the two quantities \mathbf{N} and \mathcal{M}_n . They show the allowed direction of propagation of the corresponding fronts and how much they deviate from the characteristic surfaces. They both depend on the unit vector \mathbf{n} , i.e., on the particular

FIG.3 Normal slice of the Riemann Invariant Manifold $R_n = \text{const}$ and the characteristic manifolds. Their relative position is determined by the parameter \mathcal{M}_n . When $|\mathcal{M}_n| \leq 1$, the surface element is time-like. This is an example of a space-like surface.

choice of Riemann Invariant Manifold. Using the definition of \mathcal{M}_n (38) and the equations of motion (1), one can show that

$$\mathcal{M}_n \equiv \frac{\mathbf{n} \cdot \nabla p + \rho a \nabla \cdot \mathbf{u}}{|\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}|} = \frac{\mathbf{n} \cdot \nabla p - \frac{1}{a} \frac{Dp}{Dt}}{|\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}|}, \quad (41)$$

where D/Dt denotes the Lagrangian derivative. It is interesting that the magnitude of \mathcal{M}_n depends directly on the difference between the pressure gradient in the \mathbf{n} direction and the pressure change along the fluid-particle streamline. For the case of zero-entropy gradient, it is easy to show that

$$\mathcal{M}_n = \frac{\mathbf{n} \cdot \nabla W + \nabla \cdot \mathbf{u}}{|\nabla W + (\nabla \mathbf{u})^T \mathbf{n}|} = -\frac{1}{a |\nabla R_n|} \frac{DR_n}{Dt}. \quad (42)$$

The starting point of this discussion has been Eq. (12); i.e.,

$$\frac{\partial R_n}{\partial t} + (\mathbf{u} + a\mathbf{n}) \cdot \nabla R_n + a [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}] = 0. \quad (43)$$

This equation is a first-order differential equation for the function $R_n = R_n(t, \mathbf{x})$. See appendix for details. It resembles a Hamilton-Jacobi equation similar to the one satisfied by the characteristic manifolds. The Hamiltonian in this case is seen to be

$$H(\mathbf{x}, \mathbf{p}) = (\mathbf{u} + a\mathbf{n}) \cdot \mathbf{p} + aG_n, \quad (44)$$

where

$$\mathbf{p} \equiv \nabla R_n. \quad (45)$$

The only complication here is that this equation is not independent of the others in the system. Nevertheless, conclusions can be drawn about the geometry of the integral manifold in $(N+2)$ -dimensional space (t, \mathbf{x}, R_n) or more importantly, about the geometry of the slices $R_n = \text{const}$ in spacetime (t, \mathbf{x}) , using the insight gained from the study of 1st order PDEs and in particular, the Hamilton-Jacobi equation. If one applies the results obtained for the Hamilton-Jacobi equation to Eq. (43), formally, then Eqs. (A.21) and (A.22) of the appendix give

$$\begin{aligned} \dot{\mathbf{x}}(t) &= \frac{\partial H}{\partial \mathbf{p}} = \mathbf{u} + a\mathbf{n}, \\ \dot{\mathbf{p}}(t) &= -\frac{\partial H}{\partial \mathbf{x}}, \\ \dot{R}_n(t) &= -aG_n = -a[\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}]. \end{aligned} \quad (46)$$

The integral manifold of (43) can be conveniently visualized, locally, as a network of surfaces $R_n = \text{const}$. See Fig. 4. Eqs. (46) describe how R_n changes along the bicharacteristic directions $\dot{\mathbf{x}}(t) = \mathbf{u} + a\mathbf{n}$. The bicharacteristic curves do not lie on the surfaces $R_n = \text{const}$. Recall that the vector \mathbf{n} is a constant, which labels the particular network of Riemann Invariant Manifolds. If it is possible to find a vector \mathbf{n} such that $G_n = 0$, then the bicharacteristics lie on the surfaces $R_n = \text{const}$. It is important to keep in mind that the integral curves of the vector field $\dot{\mathbf{x}}(t) = \mathbf{u} + a\mathbf{n}$, with \mathbf{n} a constant vector, are not the bicharacteristics. They are very close to the bicharacteristics for a short time. In order to remain on a bicharacteristic, the vector \mathbf{n} must change according to the second of Eqs. (46).

In general, integrating Eqs. (46) to find the solution at a point P (see Fig. 4), provides no computational advantage. It is apparent from the figure that there are an infinity of paths C on the surfaces $R_n = \text{const}$ that can be used instead. The problem of finding the solution at P reduces to computing the geometry of the curves accurately, by integrating

$$\dot{\mathbf{x}}(t) = \mathbf{V} = \mathbf{u} + a\mathbf{n} + \mathbf{v} . \quad (47)$$

All such paths C are not equivalent numerically. The local curvature of these surfaces is also an important consideration in choosing the most convenient path for numerical integration. One can try to minimize the numerical error by varying the direction of approach to the point P . It is also possible to estimate the curvature of a particular path and to use this information to achieve higher-order accuracy in the integration of (47). Moreover, by varying the vector \mathbf{n} , *i.e.*, varying the network of Riemann Invariant Manifolds, it is possible to optimize the scheme even further. The algebraic parameter \mathcal{M}_n shows whether the surface $R_n = \text{const}$ is space-like or time-like. Surfaces with $\mathcal{M}_n \gg 1$ should be avoided, because the timestep required to integrate Eq. (47) accurately would be too restrictive.

It is possible to find the projection of an arbitrary path $\dot{\mathbf{x}}(t) = \mathbf{W}$ on the surface $R_n = \text{const}$. The projection is defined to be the path $\dot{\mathbf{x}}(t) = \mathbf{V}_w$ on $R_n = \text{const}$, such that $|\mathbf{v}^\perp|$ is minimum, where

$$\mathbf{v}^\perp \equiv \mathbf{V}_w - \mathbf{W} . \quad (48)$$

Since the projection is on the Riemann Invariant Manifold,

$$\mathbf{V}_w = \mathbf{u} + a\mathbf{n} + \mathbf{v}_w , \quad (49)$$

where \mathbf{v}_w satisfies the compatibility condition (35). It is straightforward to show that

$$\mathbf{v}^\perp \cdot \mathbf{N} = \mathbf{u} \cdot \mathbf{N} + \mathcal{M}_n a - \mathbf{N} \cdot \mathbf{W} . \quad (50)$$

It is seen from Eq. (50) that $|\mathbf{v}^\perp|$ is minimum when $\mathbf{v}^\perp \parallel \mathbf{N}$. The projection is then

$$\mathbf{V}_w = (\mathbf{u} \cdot \mathbf{N} + \mathcal{M}_n a) \mathbf{N} + \mathbf{W} - (\mathbf{N} \cdot \mathbf{W}) \mathbf{N} . \quad (51)$$

FIG.4 The integral manifold of Eq. (43) is shown as a network of Riemann Invariant Manifolds $R_n = \text{const}$ in three-dimensional spacetime. It is more convenient to integrate along paths C on these surfaces rather than along the bicharacteristic paths $\dot{x}(t) = u + a\mathbf{n}$.

Now, one can find the projection of an arbitrary bicharacteristic direction $\mathbf{u} + a\hat{\mathbf{n}}$, where $\hat{\mathbf{n}}$ is a unit vector. Substituting $\mathbf{W} = \mathbf{u} + a\hat{\mathbf{n}}$ in Eq. (51) gives the projection of the bicharacteristic,

$$\mathbf{V}_p = \mathbf{u} + \mathcal{M}_n a \mathbf{N} + a [\hat{\mathbf{n}} - (\hat{\mathbf{n}} \cdot \mathbf{N}) \mathbf{N}] . \quad (52)$$

Fig. 5 shows the projection of the characteristic conoid on a particular surface $R_n = \text{const}$, which is space-like; i.e., $|\mathcal{M}_n| > 1$. It is reasonable to try to use paths contained in the projected conoid for computational purposes. The paths given by Eqs. (36) and (39) are in this projection.

Using Eq. (52), it is easy to examine the intersection of the manifold $R_n = \text{const}$ and the local characteristic ray cone. This is done by requiring

$$\mathbf{V}_p = \mathbf{u} + a\hat{\mathbf{n}} . \quad (53)$$

In other words, the projection vector \mathbf{V}_p , tangent to the Riemann Invariant Manifold, is required to be a bicharacteristic vector. From Eq. (52) it is seen that one must have

$$\hat{\mathbf{n}} \cdot \mathbf{N} = \mathcal{M}_n. \quad (54)$$

Since $\hat{\mathbf{n}}$ and \mathbf{N} are unit vectors, this equation has a solution only when $-1 \leq \mathcal{M}_n \leq 1$, *i.e.*, when the Riemann Invariant Manifold is time-like or characteristic. This is to be expected because, by definition, a space-like surface element cannot intersect the local characteristic ray cone. It is interesting that when the surface element is not space-like, it is possible to find bicharacteristic directions along which an equivalent, one-dimensional problem holds. This situation would be the direct extension of the method of characteristics to multidimensional flows, as it has been attempted in the past. A special solution is the one discussed earlier for the case $\hat{\mathbf{n}} = \mathbf{n}$. In this case Eq. (54) reduces to

$$\mathbf{n} \cdot \mathbf{N} = \mathcal{M}_n. \quad (55)$$

Using Eq. (40),

$$\mathbf{n} \cdot \mathbf{N} = \mathcal{M}_n \Rightarrow G_n = [\nabla \cdot \mathbf{u} - \mathbf{n} \cdot (\nabla \mathbf{u}) \mathbf{n}] = 0. \quad (56)$$

Yet another way to visualize the relative position of the Riemann Invariant surfaces and the characteristic manifolds is to examine the cone generated by the vector field (47) in relation to the characteristic ray cone generated by the bicharacteristic vector field. The Riemann Invariant cone is generated by varying the unit vector \mathbf{n} . It will be different for the different possible choices of \mathbf{V} on each surface $R_n = \text{const.}$ Examples are shown for the case of two-dimensional flow in Figs. (6)–(9). The direction chosen for these examples is that given by Eq. (36). Moreover, the point of interest is located at $(x, y) = (0, 0)$, the pressure is $p = 1$, the density is $\rho = 1$ and the velocity is $(u, v) = (0.5, 0.5)$. The plots shown are slices $t = 1$ of the two cones, *i.e.*, the so-called ray surfaces. The bicharacteristic ray surface is a circle.

FIG.5 The projection of the characteristic conoid at P , on the manifold $R_n = c_1$, is shown for the particular case $|\mathcal{M}_n| > 1$. It is contained between the curves C_- and C_+ .

2.4 RIM Decomposition

The geometrical picture given above suggests an algorithm for integrating the Euler equations by finding appropriate integration paths in spacetime. The previous analysis can also be viewed in a slightly different way. The original compressible Euler equations have been substituted by the following equivalent system

$$\begin{aligned} \frac{\partial R_n}{\partial t} + (\mathbf{u} + \mathcal{M}_n a \mathbf{N}) \cdot \nabla R_n &= 0 \\ \frac{\partial R_0}{\partial t} + \mathbf{u} \cdot \nabla R_0 &= 0, \end{aligned} \quad (57)$$

where

$$\mathcal{M}_n = \frac{\mathbf{n} \cdot \nabla p + \rho a \nabla \cdot \mathbf{u}}{|\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}|},$$

FIG.6 The bicharacteristic ray surface in relation to the Riemann Invariant ray surface for the case $\nabla u = (1, 0)$, $\nabla v = (-1, 0)$ and $\nabla p = (1, 2)$.

FIG.7 The bicharacteristic ray surface in relation to the Riemann Invariant ray surface for the case $\nabla u = (5, 2)$, $\nabla v = (1, -6)$ and $\nabla p = (1, -2)$.

FIG.9 The bicharacteristic ray surface in relation to the Riemann Invariant ray surface for the case $\Delta u = (7, -5)$, $\Delta v = (-6, -7)$ and $\Delta p = (5, -7)$.

FIG.8 The bicharacteristic ray surface in relation to the Riemann Invariant ray surface for the case $\Delta u = (2, 3)$, $\Delta v = (-2, 4)$ and $\Delta p = (0, 0)$.

$$\mathbf{N} = \frac{\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}}{\left| \nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n} \right|}.$$

This is a decomposition into a set of scalar fields, which is different from the characteristic decomposition (14). This decomposition strictly holds when *the spatial gradients are continuous*. This is not as serious a limitation as one might think, at first. The usual characteristic decomposition strictly holds when *the solution is continuous, i.e.*, there are no shocks present. Nevertheless, it is still used in a useful way when shocks are present because it holds on either side where the flow is smooth. The situation is analogous for the RIM decomposition. From a computational point of view one can formally try to discretize these equations in a way that is consistent with a conservative discretization of the original equations, has a prescribed order of accuracy and does not create spurious oscillations in the presence of discontinuities.

An interesting question to ask is: what new information exists in this decomposition that is not already available in the characteristic decomposition and therefore why would this be useful? From the analysis it can be seen that a great deal more information is contained in the spatial gradients of the flow. The question of asking whether there are paths along which Riemann Invariants exist, naturally led to explicit expressions of special combinations of the gradients that are important in finding solutions. It is the combination given in the Mach-like parameter \mathcal{M}_n and unit vector \mathbf{N} that determine speed and direction of propagation of information that is sufficient to determine the solution. Higher order geometrical quantities, such as local curvature can also be attained from the equations of motion. It is important to note that the information carried by the RIM waves is not the minimum or in any sense the optimal amount of information needed to generate solutions. It is *sufficient* under the smoothness assumptions. The RIM waves potentially carry more information than the characteristic waves and are free of charge, since one has explicit expressions for their properties directly from the Euler equations, without having to integrate them first. One could try to find contour levels of other quantities that could be used to construct solutions. More often than not, explicit expressions for their geometrical properties cannot be found. Moreover, the RIM

decomposition provides more information than what exists in the gradients and could be recovered, say, by a Taylor expansion. This can be seen by looking at the propagation direction \mathbf{N} as a function of the unit vector \mathbf{n} . This mapping is not bijective, which means that the range of possible propagation directions may be limited. As \mathbf{n} varies on the unit sphere for 3-D flow, \mathbf{N} does not necessarily attain all values on the unit sphere. This range of directions is given explicitly in the RIM decomposition of the Euler equations if the gradients are known. A Taylor expansion does not give preferred directions.

As an example consider the case of subsonic flow. The local characteristic analysis suggests that information from all possible directions needs to be taken into account to construct a solution. We have an “elliptic”-type behavior. The RIM decomposition and knowledge of the local spatial gradients shows whether all this information is really needed. It is possible in some parts of subsonic flow to have *sufficient* information propagating from a particular region of the flow and, thus, have “hyperbolic”-type behavior in subsonic flow. If one likes to think, physically, in terms of characteristic waves, the situation is that the characteristic waves approaching from all possible directions have to combine and interact in such a way that the only information really used is the one approaching from the allowed region. Everything else will cancel out. There is no choice under this smoothness assumption. This is a compatibility condition enforced by the Euler equations. Therefore, the RIM decomposition may not always be “better” everywhere in the flow, but it is additional information that can be used to great advantage.

Examining waves of invariants may also be useful for other reasons. It has been noticed recently that applying boundary conditions on the invariants of the inviscid Euler equations in spectral calculations of the Navier-Stokes equations is the only way to achieve numerical stability. See, *e.g.*, Don and Gottlieb (1989). Although in 1-D flows the characteristic decomposition works well, for multidimensional calculations the RIM decomposition may be the best at boundaries. The RIM decomposition also transforms the problem of integrating the Euler equations into a geometrical problem of integrating paths in spacetime. This is exactly what the method of characteristics achieves in one-dimensional flow and that is why the

RIM decomposition can be considered as the extension of that method to the multidimensional case.

It is also important to notice that the second equation in (57), *i.e.*, the entropy wave equation is unaffected by the RIM analysis. Entropy waves propagate with the fluid velocity and that does not change. This equation is irrelevant only in the case of homentropic flow as in the one-dimensional case. In the context of numerical applications this means that the RIM analysis does not provide any additional information for this particular equation.

3. Riemann Invariant Manifolds and Domain of Dependence

It is important, at this point, to make some remarks about the information that is provided by the local geometry of these Riemann Invariant Manifolds. The fluid velocity u and the speed of sound a provide information about the local geometry of the characteristic surfaces. In particular, they give the local, bicharacteristic cone. The significance of the characteristic surfaces is discussed in the appendix. Their interpretation as waves of derivative discontinuities is important. What is more significant is the role they play in proving the existence and uniqueness of solutions. The characteristic surfaces determine the domains of dependence and influence of the solution. The concepts of domains of dependence and influence are a direct result of the assumptions and results of these theorems.

Knowledge of the local, spatial gradients in the flow provides additional information, as seen in the RIM decomposition. It is important to note that the solutions at points on these manifolds are related in a simple way and that these relations can be used to determine the solution at a given point, say, numerically. What may appear disturbing, at first sight, is that these manifolds may be space-like. In other words, the solution at some point may be computed from the data at points outside its domain of dependence. See, for example, Fig. 8. Actually, in the case of zero-entropy gradients, there is a simple, explicit algebraic expression relating points connected by space-like paths in spacetime given by the Riemann Invariant

$R_n = W + \mathbf{u} \cdot \mathbf{n}$. It then becomes trivial to compute the solution at a given point from the solution at points on these Riemann Invariant Manifolds. The difficulty is transferred to the task of finding the exact location of the relevant points by integrating $\dot{\mathbf{x}}(t) = \mathbf{V}$. In any case, no matter what their exact location is, these points are going to be outside the domain of dependence, if the Riemann Invariant Surface is space-like. There appears to be a disturbing inconsistency with the concept of domain of dependence as described in the uniqueness theorems. Fig. 10 is a simplified, one-dimensional picture illustrating this situation. The solution at point P is computed by using the known solution at points Q_1 and Q_2 outside the domain of dependence D .

FIG.10 The solution at point P is related trivially through the Riemann Invariant functions to the solution at points Q_1 and Q_2 , which are outside the domain of dependence D .

Careful examination of the existence and uniqueness theorems for these hyperbolic systems of equations shows that there is really no such inconsistency. It is true that if the data in D are different, then the solution at P will change. But so will the paths Q_1P and Q_2P . What seems odd at first is that even though the data in D are sufficient to determine the solution at P , there are points outside D where the data are "related" to the solution at P . The uniqueness statement is

that points outside D cannot affect the solution at P . This is usually interpreted as meaning that any relation between the data outside D and at P must be completely random, depending on the data on the surface $t = 0$. This is not true. The local, spatial gradients determine a local relation of this form along space-like paths. The data in D are sufficient to determine the solution at P , and if the data in D are altered, the solution at P will change. Nevertheless, the solution at P is not completely unrelated to the data outside D . This has to do with the fact that knowledge of the local spatial gradients and their smoothness constitutes additional information about how the initial data on $t = 0$ are related. The uniqueness proofs are based on requiring the absolute minimum in terms of smoothness restrictions on the data. The data are simply required to be continuous. Discontinuities in the derivatives are allowed, and it was shown that these discontinuities are propagated by the characteristic surfaces. Other singularities in the derivatives also propagate along the characteristic surfaces. If the data are allowed to have jump discontinuities, then these jumps will propagate along the shock manifolds. The characteristic surfaces separate the regions of spacetime, where the derivatives of the solution are continuous. It is in these regions that knowledge of the gradients provides additional information about the solution. This additional information is conveniently visualized through the geometry of the Riemann Invariant Manifolds and can be used for computational purposes.

Those familiar with numerical methods for integrating hyperbolic equations are aware of the CFL stability condition which states, in effect, that data outside the domain of dependence must be used to achieve numerical stability. The previous discussion has nothing to do with this notion of numerical stability. Given the smoothness condition, data outside the domain of dependence may be used as prescribed in the RIM decomposition and this has nothing to do with numerics. It suggests an interesting physical relation between the concept of smoothness and that of speed of propagation of information, which is a prevalent concept in modern physics, *e.g.*, in the theory of relativity.

4. Conclusions

A new approach for studying wave propagation phenomena in an inviscid gas has been presented. The RIM wave decomposition, in general, provides more information and insight than the familiar characteristic decomposition. This decomposition is a local one and is not used to construct global solutions of the Euler equations, but it transforms the problem of integrating the Euler equations into a geometrical problem of integrating paths in spacetime. This is exactly what the method of characteristics achieves in one-dimensional flow and that is why the RIM decomposition can be considered as the extension of that method to the multidimensional case.

There is no unique, numerical implementation of these ideas. The theory suggests that the 1-D characteristic problem may be used along trajectories that lie on the Riemann Invariant Manifolds. This is a necessary constraint, but additional degrees of freedom are available for picking a numerical scheme.

APPENDIX A

Hyperbolic Systems

A.1 Characteristic Surfaces

A brief summary of the theory of hyperbolic equations in many independent variables and the theory of characteristic surfaces is presented here to serve as background. For a more detailed exposition, see Courant and Hilbert (1963). The practical problem of interest is the unsteady flow of a compressible fluid in more than one space dimension. This is a specific case of the general hyperbolic system of equations in several independent variables of the form

$$\frac{\partial U}{\partial t} + \frac{\partial F_m(U)}{\partial x_m} = 0 \quad m = 1, \dots, N, \quad (\text{A.1})$$

where $U \in \mathbb{R}^M$ is the M -dimensional solution vector, N is the spatial dimension of the problem and (F_m) is the flux vector. Time has been chosen as a special independent variable, and the summation convention is assumed. Eq. (A.1) describes a conservation law and is equivalent to the following quasi-linear form

$$\frac{\partial U}{\partial t} + A_m \frac{\partial U}{\partial x_m} = 0 \quad m = 1, \dots, N, \quad (\text{A.2})$$

where the A_m are the Jacobian matrices, given by

$$A_m \equiv \frac{\partial F_m(U)}{\partial U}. \quad (\text{A.3})$$

A linear system is one for which the matrices A_m are independent of the solution U . The solution is also assumed to be sufficiently smooth for all operations performed to have meaning.

It is sometimes useful not to single out the time variable t . The advantage of this is that the conservation law, Eq (A.1), takes the particularly simple form of a divergence in spacetime,

$$\frac{\partial F_\mu(U)}{\partial x_\mu} = A_\mu \frac{\partial U}{\partial x_\mu} = A_0 \frac{\partial U}{\partial t} + A_m \frac{\partial U}{\partial x_m} = 0 \quad \mu = 0, 1, \dots, N, \quad (\text{A.4})$$

where $x_0 \equiv t$. Greek subscripts will be used when time is not singled out as a special variable. In what follows, A_0 is usually taken to be the identity matrix I . It is also useful sometimes to write (A.1) and (A.2) using absolute notation,

$$\begin{aligned} \frac{\partial U}{\partial t} + \nabla \cdot \mathbf{F}(U) &= 0 \\ \frac{\partial U}{\partial t} + \mathbf{A} \cdot \nabla U &= 0, \end{aligned} \quad (\text{A.5})$$

where

$$\begin{aligned} \nabla &\equiv \left(\frac{\partial}{\partial x_m} \right) \\ \mathbf{F} &\equiv (F_m) \\ \mathbf{A} &\equiv (A_m). \end{aligned} \quad (\text{A.6})$$

In order for this system of equations to be hyperbolic, the matrices A_m must satisfy certain conditions. The concept of hyperbolicity is related to the existence of special surfaces in spacetime, which are called characteristic surfaces. The quest for such surfaces is motivated by the Cauchy Initial Value Problem (IVP) for Eq. (A.2). Consider a surface $\varphi(t, \mathbf{x}) = 0$, $\mathbf{x} \in \mathbb{R}^N$, in spacetime. The Cauchy IVP consists in specifying initial data U on this surface and using Eq. (A.2) to find the solution $U = U(t, \mathbf{x})$ off the surface. The natural question to ask is whether this is possible for any surface $\varphi(t, \mathbf{x}) = 0$.

For visualization purposes, it is convenient to consider the special case $N = 2$. Spacetime is now a three-dimensional space. See Fig. A.1.

Consider the general coordinate transformation

$$\begin{aligned} \varphi &= \varphi(t, \mathbf{x}) \\ \psi_k &= \psi_k(t, \mathbf{x}) \quad k = 1, \dots, N, \end{aligned} \quad (\text{A.7})$$

FIG.A.1 The surface $\varphi(t, \mathbf{x}) = 0$ in three-dimensional spacetime.

where the given surface $\varphi(t, \mathbf{x}) = 0$ is used as one of the new coordinate surfaces. The transformation is assumed to be smooth, with a non-vanishing Jacobian at the points of interest. It is easy to see that

$$\begin{aligned} \frac{\partial U}{\partial t} &= \frac{\partial \varphi}{\partial t} \frac{\partial U}{\partial \varphi} + \frac{\partial \psi_k}{\partial t} \frac{\partial U}{\partial \psi_k} \\ \frac{\partial U}{\partial x_m} &= \frac{\partial \varphi}{\partial x_m} \frac{\partial U}{\partial \varphi} + \frac{\partial \psi_k}{\partial x_m} \frac{\partial U}{\partial \psi_k}, \end{aligned} \quad (\text{A.8})$$

where U is now considered a function of the new variables; i.e., $U = U(\varphi, \psi_k)$. Substituting Eqs. (A.8) in (A.2), one finds

$$\left(\frac{\partial \varphi}{\partial t} I + \frac{\partial \varphi}{\partial x_m} A_m \right) \frac{\partial U}{\partial \varphi} + \left(\frac{\partial \psi_k}{\partial t} I + \frac{\partial \psi_k}{\partial x_m} A_m \right) \frac{\partial U}{\partial \psi_k} = 0. \quad (\text{A.9})$$

Assume that initial data are given on $\varphi = 0$. Then all the tangential derivatives

$$\frac{\partial U}{\partial \psi_k}, \quad k = 1, \dots, N,$$

are known from the initial data, and only the derivative in the normal direction, i.e.,

$$\frac{\partial U}{\partial \varphi},$$

is unknown. This normal derivative can be found by solving for it in Eq. (A.9). By differentiating (A.9), similar algebraic equations can be found for the higher-order derivatives of U in the normal direction. One can, then, use these derivatives to construct the solution off the $\varphi = 0$ surface with the aid of a Taylor series expansion.

It can be seen from Eq. (A.9) that it is not possible to solve for the unknown derivative when

$$Q \equiv \det \left(\frac{\partial \varphi}{\partial t} I + \frac{\partial \varphi}{\partial x_m} A_m \right) = \det \left(\frac{\partial \varphi}{\partial x_\mu} A_\mu \right) = 0. \quad (\text{A.10})$$

A surface for which (A.10) holds, is called a *characteristic surface*. Q is a function of the first derivatives of φ and is called the *characteristic function*. $Q = 0$ is a first-order, differential equation for the function $\varphi = \varphi(t, \mathbf{x})$. Although Eq. (A.10) must hold only for $\varphi = 0$, one can embed this surface in the family of $\varphi = \text{const}$ surfaces. This family is the solution of the first-order, partial-differential equation (A.10). Note that all these relations are local. This is particularly important for nonlinear problems for which the matrices A_μ and thus the characteristic surfaces, depend on the solution U .

From the previous discussion it follows that the derivative of the solution normal to a characteristic surface cannot be determined by the differential equation and therefore, a discontinuity in this derivative is possible. The same holds for all higher-order, normal derivatives. Thus, one can define the characteristic surfaces as the surfaces across which discontinuities in the derivatives of the solution are possible. This definition is a little restrictive, because it implies that the characteristic surfaces are significant only when discontinuities are present, which is not the case.

A more useful definition is that characteristic surfaces are the surfaces on which the differential operator in (A.2) may become an "internal" operator. What is meant by this is seen from the transformed system (A.9). If

$$\left(\frac{\partial \varphi}{\partial t} I + \frac{\partial \varphi}{\partial x_m} A_m \right) \frac{\partial U}{\partial \varphi} = 0, \quad (\text{A.11})$$

for a particular vector $\frac{\partial U}{\partial \varphi}$, then the system of equations contains only derivatives on the surface, *i.e.*, no normal derivatives. For Eq. (A.11) to hold for a non-trivial value of the normal derivative, the surface $\varphi = 0$ must satisfy the condition given by (A.10); *i.e.*, it must be characteristic.

The differential operator

$$D \equiv A_\mu \frac{\partial}{\partial x_\mu} = I \frac{\partial}{\partial t} + A_m \frac{\partial}{\partial x_m}, \quad (\text{A.12})$$

is hyperbolic if real characteristic surfaces exist. This requirement can be made more specific by defining

$$\begin{aligned} \mathbf{n} &\equiv \nabla \varphi / |\nabla \varphi| \\ \lambda &\equiv -\frac{\partial \varphi}{\partial t} / |\nabla \varphi|, \end{aligned} \quad (\text{A.13})$$

where $\nabla \varphi$ is the spatial gradient of φ . Substituting in (A.10) one finds

$$\hat{Q} = \hat{Q}(\mathbf{n}, \lambda) \equiv \det(n_m A_m - \lambda I) = 0, \quad (\text{A.14})$$

which is the characteristic equation for the eigenvalue problem associated with the matrix $\mathbf{n} \cdot \mathbf{A} \equiv n_m A_m$. Given a spatial unit vector \mathbf{n} , if the eigenvalues λ_m , $m = 1, \dots, M$, of $\mathbf{n} \cdot \mathbf{A}$ are real, then the operator D is hyperbolic. This must hold for any unit vector \mathbf{n} . The right eigenvectors of this matrix will be denoted by r_m and the left eigenvectors by l_m . Thus,

$$\begin{aligned} (\mathbf{n} \cdot \mathbf{A}) r_m &= \lambda_m r_m \\ (\mathbf{n} \cdot \mathbf{A})^T l_m &= \lambda_m l_m \end{aligned} \quad m = 1, \dots, M \quad (\text{No summation on } m). \quad (\text{A.15})$$

The characteristic function Q (or \hat{Q}) is of the form

$$Q = Q_1^{k_1} Q_2^{k_2} \dots Q_p^{k_p}, \quad k_j \in \mathbb{Z}^+, \quad j = 1, \dots, p. \quad (\text{A.16})$$

This is because the characteristic function is a polynomial in the derivatives of φ . The j^{th} factor in (A.16) corresponds to a particular type of characteristic manifold for the differential operator and to a particular eigenvalue λ_j in (A.14). k_j is the degeneracy of λ_j and the corresponding characteristic manifold. The j^{th} factor can be written, in general, as

$$Q_j = \frac{\partial \varphi}{\partial t} + H_j(\mathbf{x}, \nabla \varphi; U) = 0. \quad (\text{A.17})$$

The characteristic equation (A.17) is a first-order, partial-differential equation of the general form

$$F\left(x_\alpha, \varphi, \frac{\partial \varphi}{\partial x_\beta}\right) = 0, \quad \alpha, \beta = 0, 1, \dots, N \quad (\text{A.18})$$

for the function $\varphi = \varphi(x_\alpha)$. An extensive theory exists for such equations; *e.g.*, see Courant and Hilbert (1963). The solution of (A.18) is a surface in the $(N + 2)$ -dimensional space (φ, x_α) .

It is important to note that this integral surface can be generated by a family of characteristic curves. An important special case of (A.18) is the Hamilton-Jacobi equation, which arises in many applications in physics, the best known being the Hamiltonian formulation of classical mechanics. This differential equation has a variational problem associated with it. The general form of the Hamilton-Jacobi equation is

$$\frac{\partial \varphi}{\partial t} + H(t, \mathbf{x}, \mathbf{p}) = 0, \quad (\text{A.19})$$

where H is the corresponding Hamiltonian function and \mathbf{p} is defined as

$$\mathbf{p} \equiv \nabla \varphi. \quad (\text{A.20})$$

The variable $x_0 = t$ is singled out as a special independent variable, usually time. Eq. (A.17) for the j^{th} characteristic manifold is of this form, with no explicit dependence of the Hamiltonian on time. The action in the Hamiltonian formulation of classical mechanics also satisfies an equation of this form. The space dimension N corresponds to the degrees of freedom of the mechanical system and \mathbf{p} , which is the spatial gradient of φ , corresponds to the generalized momentum. The following canonical system of ordinary differential equations,

$$\begin{aligned} \dot{\mathbf{x}}(t) &= \frac{\partial H}{\partial \mathbf{p}} \\ \dot{\mathbf{p}}(t) &= -\frac{\partial H}{\partial \mathbf{x}}, \end{aligned} \quad (\text{A.21})$$

can then be used to generate the integral manifold $\varphi = \varphi(t, \mathbf{x})$ from some initial N -dimensional manifold in the space (t, \mathbf{x}, φ) . Eqs. (A.21) are used to find the trajectory $\mathbf{x} = \mathbf{x}(t)$ and $\mathbf{p} = \mathbf{p}(t)$ of the mechanical system in the phase space (\mathbf{x}, \mathbf{p}) . They define the characteristic strips for the Hamilton-Jacobi Equation (A.19). From Eqs. (A.19) and (A.21), we see that along these paths in phase space,

$$\dot{\varphi}(t) = \dot{\mathbf{x}}(t) \cdot \mathbf{p}(t) - H[t, \mathbf{x}(t), \mathbf{p}(t)] . \quad (\text{A.22})$$

The right-hand side of Eq. (A.22) is equal to the Lagrangian of classical mechanics. For the special Hamilton-Jacobi Equation (A.17), which arises from the study of the characteristic surfaces of (A.1), it can be shown that $\dot{\varphi}(t) = 0$. Hence, the trajectories $\mathbf{x} = \mathbf{x}(t)$ in N -dimensional space lie on $\varphi(t, \mathbf{x}) = \text{const}$ surfaces, *i.e.*, on the characteristic surfaces. These trajectories are called the rays of the characteristic surfaces and the bicharacteristics of the original system of differential equations.

Any surface $\varphi(t, \mathbf{x}) = 0$ in spacetime, *e.g.*, the one shown in Fig. A.1, can be interpreted as a wave front. Fig. A.2 shows a two-dimensional front, which is equivalent to a surface $\varphi = 0$ in three-dimensional spacetime. Given the front location at time t , the motion can be described using the position vector $\mathbf{x} = \mathbf{X}(s, t)$, where s is a convenient parameter, say, the arclength of the front at the initial time t . The unit normal \mathbf{n} is the one defined in (A.13). This description of a surface in spacetime is equivalent to the function $\varphi(t, \mathbf{x}) = 0$, but is sometimes more convenient. It shows how such a surface can be interpreted as a wave front, and in the case of characteristic surfaces, it makes more clear their interpretation as waves of discontinuities of the derivatives of the solution. The velocity of the front is defined by

$$\mathbf{V}(s, t) = \frac{\partial \mathbf{X}}{\partial t}(s, t) . \quad (\text{A.23})$$

It is interesting to note that the motion of the front is specified by the normal front velocity $\mathbf{n} \cdot \mathbf{V}$ only. A tangential velocity component can be added without changing the location of the front at some later time $t + \Delta t$. See Fig. A.2. This is equivalent to redefining the parameter s of the front at the initial time t .

FIG.A.2 A two-dimensional front at times t and $t + \Delta t$. This front is described by the position vector $\mathbf{X}(s, t)$ and is equivalent to the surface $\varphi(t, \mathbf{x}) = 0$ in three-dimensional spacetime.

For the case of characteristic fronts, there is a special local direction that can be used to assign a tangential velocity component. That is the direction of the characteristic rays of the surface $\varphi(t, \mathbf{x}) = 0$ corresponding to this front. The characteristic rays are given by the first of the canonical set of Equations (A.21). This is possible only because the characteristic rays lie on the surface $\varphi = 0$; i.e., $\varphi[t, \mathbf{x}(t)] = 0$. It is important to note that from a computational point of view, generating the surface $\varphi = 0$ locally should be done using the most convenient set of curves. These do not always coincide with the characteristic rays.

The first of Eqs. (A.21) defines a vector field in spacetime given by

$$\dot{\mathbf{x}}(t) = \frac{\partial H}{\partial \mathbf{p}}(\mathbf{x}, \mathbf{p}) .$$

Actually, at every point in spacetime there is a family of vectors, since there is a dependence on the generalized momentum $\mathbf{p} = \nabla\varphi$. It is easy to visualize this in the special case of three-dimensional spacetime. It can be seen that for every possible orientation of the unit normal \mathbf{n} in Fig. A.2, which is related to \mathbf{p} through (A.13),

there is a different bicharacteristic direction. These directions form the so-called ray cone at every point. By integrating in time, the bicharacteristic curves emanating from a point form the ray conoid, which is essentially the conical solution of the characteristic Hamilton-Jacobi equation. See Fig. A.3. The ray cone is tangent to the ray conoid.

FIG.A.3 The ray conoid through the point P determines the domain of dependence D and the domain of influence I of the solution at P .

Insofar as a characteristic surface can be interpreted as a wave, the characteristic conoid emanating from a point can be considered a wave front generated by a disturbance at this point. This characteristic conoid is tangent to all characteristic surfaces that pass through the given point. Moreover, the intersection of this conoid with the hyperplanes $t = \text{const}$ determines the domain of dependence D and the domain of influence I of the solution at the given point. See Fig. A.3.

One can prove the existence and uniqueness of solutions of the hyperbolic systems under consideration. These theorems show that given initial data on the

hyperplane $t = 0$, the solution at the point P cannot depend on initial data outside the domain of dependence D . Furthermore, the solution at P cannot possibly influence the solution outside the forward-facing conoid, which cuts out the domain of influence I at some later time t . The details of the proof of these theorems can be found in Courant and Hilbert (1963); Friedrichs (1954); Friedrichs and Lax (1965), and Kato (1975).

The domains D and I in Fig. A.3 are shown as simply connected. This is not necessarily the case for an arbitrary, hyperbolic system. One can define a space-like or time-like surface element passing through the point P with respect to the characteristic conoid. A surface element is space-like if its normal direction is inside the conoid, and time-like if it is not. The hyperplanes $t = \text{const}$, on which initial data are usually specified, are space-like. The Cauchy IVP has a unique solution provided initial data are specified on any space-like surface, not necessarily the hyperplanes $t = \text{const}$.

A.2 Application to Gas Dynamics

To illustrate these concepts consider the example of interest here, namely, the 3-D inviscid flow of a compressible fluid. The equations of motion can be written in the non-conservative form

$$\begin{aligned}\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) &= 0 \\ \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} + \frac{1}{\rho} \nabla p &= 0 \\ \frac{\partial p}{\partial t} + \mathbf{u} \cdot \nabla p + \rho a^2 \nabla \cdot \mathbf{u} &= 0,\end{aligned}\tag{A.24}$$

where ρ is the density, p is the pressure, $\mathbf{u} = (u, v, w)^T$ is the velocity vector and a is the speed of sound. Eqs. (A.24) can be written in the general form

$$\frac{\partial U}{\partial t} + A_x \frac{\partial U}{\partial x} + A_y \frac{\partial U}{\partial y} + A_z \frac{\partial U}{\partial z} = 0,\tag{A.25}$$

where

$$\begin{aligned}
 U &= \begin{pmatrix} \rho \\ u \\ v \\ w \\ p \end{pmatrix}, & A_x &= \begin{pmatrix} u & \rho & 0 & 0 & 0 \\ 0 & u & 0 & 0 & 1/\rho \\ 0 & 0 & u & 0 & 0 \\ 0 & 0 & 0 & u & 0 \\ 0 & \rho a^2 & 0 & 0 & u \end{pmatrix}, \\
 A_y &= \begin{pmatrix} v & 0 & \rho & 0 & 0 \\ 0 & v & 0 & 0 & 0 \\ 0 & 0 & v & 0 & 1/\rho \\ 0 & 0 & 0 & v & 0 \\ 0 & 0 & \rho a^2 & 0 & v \end{pmatrix}, & A_z &= \begin{pmatrix} w & 0 & 0 & \rho & 0 \\ 0 & w & 0 & 0 & 0 \\ 0 & 0 & w & 0 & 0 \\ 0 & 0 & 0 & w & 1/\rho \\ 0 & 0 & 0 & \rho a^2 & w \end{pmatrix}.
 \end{aligned} \tag{A.26}$$

There are five unknown functions; *i.e.*, $M = 5$, defined on 4-dimensional spacetime, *i.e.*, $N = 3$. One can easily specialize the following results to the case $N = 2$, or $N = 1$. It is a straightforward calculation to substitute (A.26) in Eq. (A.10) to find

$$Q = \left(\frac{\partial \varphi}{\partial t} + \mathbf{u} \cdot \nabla \varphi \right)^3 \left(\frac{\partial \varphi}{\partial t} + \mathbf{u} \cdot \nabla \varphi + a |\nabla \varphi| \right) \left(\frac{\partial \varphi}{\partial t} + \mathbf{u} \cdot \nabla \varphi - a |\nabla \varphi| \right) = 0. \tag{A.27}$$

The convective characteristic manifold is defined by the Hamilton-Jacobi equation

$$\frac{\partial \varphi}{\partial t} + \mathbf{u} \cdot \nabla \varphi = 0. \tag{A.28}$$

It has a 3-fold degeneracy. The acoustic characteristic manifold is defined by the equations

$$\frac{\partial \varphi}{\partial t} + \mathbf{u} \cdot \nabla \varphi \pm a |\nabla \varphi| = 0. \tag{A.29}$$

Let's examine the acoustic manifold given by (A.29) with just the plus sign. Referring to the general Hamilton-Jacobi notation, the Hamiltonian is seen to be

$$H(\mathbf{x}, \mathbf{p}) = \mathbf{u} \cdot \mathbf{p} + a |\mathbf{p}|, \tag{A.30}$$

where $\mathbf{p} = \nabla \varphi$. From the canonical ODEs (A.21), it is seen that the rays of the acoustic characteristic manifold are given by

$$\dot{\mathbf{x}}(t) = \frac{\partial H}{\partial \mathbf{p}} = \mathbf{u} + a \frac{\mathbf{p}}{|\mathbf{p}|}, \tag{A.31}$$

or by (A.13),

$$\dot{\mathbf{x}}(t) = \mathbf{u} + a \mathbf{n}. \tag{A.32}$$

These rays are the bicharacteristics for the equations of gas dynamics. They are the generators of the ray conoid. See Fig. A.3. The eigenvalues λ_m , $m = 1, \dots, 5$, of the matrix $\mathbf{n} \cdot \mathbf{A}$, are given by the second expression in (A.13); *i.e.*,

$$\lambda = -\frac{\partial \varphi}{\partial t} / |\nabla \varphi| = H(\mathbf{x}, \mathbf{p}) / |\mathbf{p}|. \quad (\text{A.33})$$

For the particular example of the acoustic manifold, the Hamiltonian is given by (A.30) and, hence the corresponding eigenvalue is

$$\lambda = (\mathbf{u} \cdot \mathbf{p} + a|\mathbf{p}|) / |\mathbf{p}| = \mathbf{u} \cdot \mathbf{n} + a. \quad (\text{A.34})$$

It is interesting that the eigenvalue λ coincides with the normal velocity component of the characteristic front. See Fig. A.2. It is also easy to show that along the bicharacteristics,

$$\dot{\varphi}(t) = \dot{\mathbf{x}}(t) \cdot \mathbf{p}(t) - H[\mathbf{x}(t), \mathbf{p}(t)] = \mathbf{u} \cdot \mathbf{p} + a|\mathbf{p}| - H = 0. \quad (\text{A.35})$$

Therefore, the bicharacteristics lie on the characteristic surfaces, as expected. Similarly, one finds that the rays of the convective manifold (A.28) are the flow streamlines

$$\dot{\mathbf{x}}(t) = \mathbf{u}. \quad (\text{A.36})$$

Riemann Invariant Manifolds for the Multidimensional Euler Equations

Part II: A Multidimensional Godunov Scheme and Applications

Tasso Lappas*, Anthony Leonard†, and Paul E. Dimotakis‡

California Institute of Technology
Pasadena, Ca 91125*

Abstract

The theory of Riemann Invariant Manifolds (RIM) is used to develop a second-order unsplit Godunov-type scheme for the compressible Euler equations. Using this theory it is possible to construct a family of conservative shock-capturing schemes that are consistent with the theory. This is demonstrated for the special case of two-dimensional flow, but the extension to three dimensions is straightforward. By choosing the Riemann Invariant Manifolds to be those corresponding to the grid line directions, it is possible to generate a scheme that is similar to a MUSCL scheme. The difference lies in the states which are eventually supplied to the one-dimensional Riemann solver at every cell interface. The appropriate Riemann Invariant Manifolds are traced back in time, locally, in each cell. This procedure provides the states that are connected with equivalent one-dimensional problems. Furthermore, by assuming a linear variation of all quantities in each computational cell, it is possible to derive explicit formulas for the states used in the one-dimensional characteristic problem.

1. Introduction

Progress has been made in recent years in the development of numerical schemes for computing hyperbolic systems of equations. Most of these schemes are based on the original Godunov scheme (1959). The main idea is to use the knowledge from the theory of characteristics, locally, in each computational cell to compute the various flux terms. By doing this, the local wave patterns are accounted for accurately. Since discontinuities are likely to be present, the characteristic problem is generalized to allow for their presence. The characteristic equations have to be discretized in a way that ensures at least second-order accuracy where the flow is smooth and is well behaved near discontinuities. The discrete equations have to be approximations to the appropriate jump conditions near shocks. This can be done by solving an appropriate Riemann problem near the interfaces of each computational cell. The solution to the Riemann problem reduces to the known characteristic problem in the absence of discontinuities. This procedure is equivalent to performing the characteristic decomposition of the Euler equations as a first step and then, discretizing the resulting scalar field equations in a way that ensures at least second-order accuracy and does not result in spurious oscillations near discontinuities.

The application of this idea is straightforward for the one-dimensional case, because the 1-D Euler equations decouple into the scalar characteristic field equations in a unique way. The extension to multidimensional flows is not that easy. Practically, these schemes are extended to more dimensions by treating the additional spatial dimensions separately. The computation is not truly multidimensional, but rather a number of separate one-dimensional computations in each spatial direction. Even schemes that appear to be multidimensional (unsplit), actually use the local directions of the grid to set up and solve a 1-D Riemann problem, thus taking advantage of the 1-D results. Efforts to create a genuinely multidimensional scheme are those by Roe (1986); Hirsch & Lacor (1989), and Deconinck *et al.* (1986). These efforts are within the context of conservative shock-capturing schemes of the Godunov type. Butler (1960) has shown a possible extension of the method of characteris-

tics for computing unsteady two-dimensional flows. This scheme is also genuinely multidimensional.

A true extension of the Godunov scheme to the multidimensional case would be achieved by solving the multidimensional Riemann problem at every computational cell. This is very difficult and it has not yet been shown to have a unique solution. Despite this, the RIM wave decomposition can be used to construct unsplit multidimensional schemes by finding states that are connected with equivalent one-dimensional problems. In what follows, the theory of Riemann Invariant Manifolds will be used to construct a conservative, shock-capturing scheme for unsteady, two-dimensional flow. The basis for the scheme is a second-order Godunov scheme (MUSCL scheme, van Leer, 1979), which is modified to take into account the multidimensional character of the flow. The numerical fluxes are computed by tracing the appropriate Riemann Invariant Manifolds back in time, in order to find the states which are related with an equivalent one-dimensional problem. This results in a multidimensional scheme without flux splitting, *i.e.*, a truly unsplit scheme. Assuming a linear variation of all quantities in each computational cell, it is possible to derive explicit formulas for the states used in the 1-D characteristic problem. In effect, the Euler equations are substituted by the scalar field equations resulting from the RIM wave decomposition. These equations are then discretized in space and time. The application of the theory is demonstrated for two-dimensional flow, but the extension to three-dimensional flow is straightforward.

In the theoretical development of the Riemann Invariant Manifolds (Part I) it was shown that the RIM decomposition strictly holds under certain smoothness assumptions. Nevertheless, the results can be used in the cases where shocks, *i.e.*, jump discontinuities, are present. This is because the resulting equations are discretized so that they are consistent with the jump conditions in the presence of shocks. The examination of these special manifolds in spacetime can also provide a means of determining spatial directions in the flow which are special in some sense. It is important to note that the theory of Riemann Invariant Manifolds can be used to construct a variety of multidimensional numerical schemes. What follows

is simply one example of how a Godunov-type scheme can be modified to take into account multidimensional effects.

2. Second-Order Godunov Scheme

A description of an Eulerian MUSCL scheme will be given, since this is the basis for the proposed multidimensional scheme. Most high-order, shock-capturing schemes have been developed using the theory of hyperbolic systems in one space dimension and time. It is therefore convenient to describe the scheme for this special 1-D case and then to show the extension to many spatial dimensions.

The goal is to solve numerically the general, nonlinear system of equations

$$\frac{\partial U}{\partial t} + \frac{\partial F(U)}{\partial x} = 0. \quad (1)$$

This is a general conservation law, where t is the time variable, x is the space variable and $U = U(t, x) \in \mathbb{R}^M$ is the conserved unknown vector. For the case of 1-D gasdynamics,

$$U = \begin{pmatrix} \rho \\ \rho u \\ \rho e_t \end{pmatrix}, \quad F(U) = \begin{pmatrix} \rho u \\ \rho u^2 + p \\ \rho u e_t + p u \end{pmatrix}, \quad (2)$$

where ρ is the density, p the pressure, u the velocity of the gas and $e_t = (e + \frac{1}{2} u^2)$ is the total energy. The internal energy e is related to the pressure p by

$$p = (\gamma - 1)\rho e, \quad (3)$$

for the case of a perfect gas with constant, specific heat ratio γ .

A finite-volume formulation is used. The spatial domain is discretized, and the average value of the conserved vector U in the j^{th} cell is denoted by U_j . Quantities associated with the two interfaces of the j^{th} cell are denoted by the subscripts $j \pm 1/2$. A general conservative scheme is of the form

$$U_j^{n+1} = U_j^n - \frac{\Delta t}{\Delta x} (\tilde{F}_{j+1/2} - \tilde{F}_{j-1/2}). \quad (4)$$

This is really an application of the integral-conservation form of Eq. (1) to the j^{th} cell. It gives the cell-averaged, conserved vector U at the time level $n + 1$ from the previous time level n . Δx is the size of the cell and Δt is the timestep. The quantities $\tilde{F}_{j\pm 1/2}$ are the time-averaged fluxes at the two cell interfaces; *i.e.*,

$$\tilde{F}_{j\pm 1/2} \equiv \frac{1}{\Delta t} \int_{t_n}^{t_n + \Delta t} F(U_{j\pm 1/2}) dt, \quad (5)$$

where $F = F(U)$ is given by Eq. (2). It is important to notice that Eq. (4) is *exact*. In a numerical scheme it is not possible to calculate the integrals given in Eq. (5) exactly. The integrals are therefore approximated, and the final numerical scheme is of the form

$$U_j^{n+1} = U_j^n - \frac{\Delta t}{\Delta x} \left(\hat{F}_{j+1/2} - \hat{F}_{j-1/2} \right), \quad (6)$$

where the quantities $\hat{F}_{j\pm 1/2}$ are the numerical approximations of the $\tilde{F}_{j\pm 1/2}$. Every conservative scheme reduces to calculating the numerical fluxes $\hat{F}_{j\pm 1/2}$ at the cell interfaces. All Godunov schemes attempt to compute these fluxes by using the knowledge from the theory of characteristics, locally, at each cell interface. By doing this, the local characteristic wave patterns are accounted for, accurately. Since discontinuities are likely to be present, the characteristic problem is generalized to allow for their presence. This constitutes the well-known Riemann problem. How this is done for the case of a second-order Godunov scheme (MUSCL) will now be described.

At any given time t_n , one has only the average values of U in each computational cell, as given by the discrete scheme (6). The first step in calculating the numerical fluxes $\hat{F}_{j\pm 1/2}$ is to reconstruct the solution at time t_n by some kind of spatial interpolation. This is a very important step, because the presence of discontinuities in these flows may cause problems. This constitutes the most important step for a variety of high-order, conservative schemes. The second step, then, is to use the knowledge of the solution at this time level to solve a local, characteristic problem in order to calculate the numerical fluxes. These two steps will be given for the MUSCL scheme.

A linear variation of the primitive variables ρ , p and u is assumed in each cell. The generic quantity q is given by

$$q(x) = q_j + (q_x)_j (x - x_j) , \quad (7)$$

in the j^{th} cell, where q_j is the average value in the cell, x_j is the center of the cell and $(q_x)_j$ is the slope of q in this cell, which is assumed to be constant. Note that discontinuities of these quantities are allowed at the cell interfaces, as shown in Fig. 1.

FIG.1 Linear variation of the generic quantity q in the j^{th} cell. In general, q is discontinuous at the cell interfaces.

The slope $(q_x)_j$ is computed, following van Leer (1984), by

$$(q_x)_j = \text{ave}(q_x^-, q_x^+) , \quad (8)$$

where

$$q_x^- = \frac{q_j - q_{j-1}}{x_j - x_{j-1}} , \quad q_x^+ = \frac{q_{j+1} - q_j}{x_{j+1} - x_j} , \quad (9)$$

$$\text{ave}(x, y) \equiv \frac{x + y}{2} \left[1 - \frac{(x - y)^2}{x^2 + y^2 + c^2} \right] , \quad (10)$$

and c^2 is a small constant ($c^2 \ll 1$). This slope-limiting procedure ensures the preservation of monotonicity in the interpolant in regions of discontinuities.

The numerical fluxes $\hat{F}_{j\pm 1/2}$ are calculated by Eq. (5), using the trapezoid rule, *i.e.*,

$$\hat{F}_{j\pm 1/2} = \frac{1}{2} \left(F \left(U_{j\pm 1/2}^n \right) + F \left(U_{j\pm 1/2}^{n+1} \right) \right), \quad (11)$$

where the superscript $n+1$ denotes the time level $t_n + \Delta t$. The problem of finding the numerical fluxes becomes that of estimating the solution vector U at the cell interfaces at times t_n and $t_n + \Delta t$. This procedure ensures second-order accuracy in time.

The domain of dependence of $x = x_{j+1/2}$ over the time interval Δt is estimated by the characteristics at the time level t . The characteristic speeds are given by

$$c_{\pm} = u \pm a, \quad c_0 = u, \quad (12)$$

where a is the speed of sound. In the example shown in Fig. 2, the flow is subsonic; *i.e.*, $c_+ > 0$ and $c_- < 0$. It is known that along the characteristics C_{\pm} the following differential equations hold:

$$\left[\frac{\partial p}{\partial t} + (u \pm a) \frac{\partial p}{\partial x} \right] \pm \rho a \left[\frac{\partial u}{\partial t} + (u \pm a) \frac{\partial u}{\partial x} \right] = 0. \quad (13)$$

These two equations are written in the more conventional form as

$$\frac{dp}{dt} \pm \rho a \frac{du}{dt} = 0, \quad (14)$$

where the time derivatives are derivatives along the appropriate characteristic directions. Along the streamline C_0 ,

$$\left[\frac{\partial p}{\partial t} + u \frac{\partial p}{\partial x} \right] - a^2 \left[\frac{\partial \rho}{\partial t} + u \frac{\partial \rho}{\partial x} \right] = 0, \quad (15)$$

or

$$\frac{dp}{dt} - a^2 \frac{d\rho}{dt} = 0, \quad (16)$$

FIG.2 The constant states, which are to be used as the initial condition for the Riemann problem at the interface $j + 1/2$, are obtained by tracing the characteristics back in time from the time level $t + \Delta t$. In this example the flow is subsonic; i.e., $c_+ > 0$ and $c_- < 0$.

which is equivalent to the statement that the entropy remains constant along the streamline. Eqs. (14) and (16) form the basis for the method of characteristics in 1-D gas dynamics. Moreover, when supplemented with the jump conditions, they form the basis for the solution of the 1-D Riemann problem.

The state $U_{j+1/2}^n$ is computed as the solution to the Riemann problem at time t_n . The two initial states are those found by extrapolating the linear interpolants (7) to the interface $j + 1/2$ on either side. The state $U_{j+1/2}^{n+1}$ is a little more complicated. The pressure $p_{j+1/2}^{n+1}$ and velocity $u_{j+1/2}^{n+1}$ are found by solving the Riemann problem with initial states those given by the points P_{\pm} in Fig. 2. This is equivalent to discretizing Eqs. (14) in a way that is consistent with the jump conditions in the presence of a shock.

The density $\rho_{j+1/2}^{n+1}$ is found by discretizing Eq. (16) in the following way;

$$\left(p_{j+1/2}^{n+1} - p_0 \right) - a_0^2 \left(\frac{\gamma + 1}{2\gamma} + \frac{\gamma - 1}{2\gamma} \frac{p_{j+1/2}^{n+1}}{p_0} \right) \left(\rho_{j+1/2}^{n+1} - \rho_0 \right) = 0, \quad (17)$$

if $p_{j+1/2}^{n+1} > p_0$ and

$$\rho_{j+1/2}^{n+1} = \rho_0 \left(\frac{p_{j+1/2}^{n+1}}{p_0} \right)^{1/\gamma}, \quad (18)$$

if $p_{j+1/2}^{n+1} < p_0$. The subscript zero refers to the state at point P_0 in Fig. 2, i.e., the state found by tracing the streamline back in time. Eq. (17) is essentially the jump condition to take care of the situation where the streamline is being traced through a shock. In the limit of weak shocks this expression gives the density change through an acoustic wave. Eq. (18) is just the isentropic relation.

There are many variations of the MUSCL scheme that arise from changing the spatial interpolation scheme or changing the way the states for the Riemann problem are chosen. A different way of picking the two states is by using a Taylor series expansion on either side of the interface $j + 1/2$. The left state of the initial condition for the Riemann problem is given by the following expansion about the center of the j^{th} cell,

$$\begin{aligned} U_L &= U_j + (x - x_c) \frac{\partial U}{\partial x} + \Delta t \frac{\partial U}{\partial t} \\ &= U_j + (x - x_c) \left(\frac{\partial U}{\partial x} \right) - \Delta t A \left(\frac{\partial U}{\partial x} \right) \\ &= U_j + [(x - x_c) I - \Delta t A] \left(\frac{\partial U}{\partial x} \right), \end{aligned} \quad (19)$$

where x_c is the center of the cell, I is the unit matrix and

$$A \equiv \frac{\partial F(U)}{\partial U}. \quad (20)$$

The spatial derivatives are constant in each cell, since a linear interpolant is used. Similarly, one finds the right state U_R by expanding in the $(j + 1)^{\text{th}}$ cell. This procedure works in practice, and it is mentioned because it can be extended to the multidimensional case in a straightforward way.

The process of tracing the characteristics back in time is the best way to find the initial condition for the Riemann problem for the 1-D case, but this procedure cannot be extended to the multidimensional case. This is a general problem of all

similar methods that use knowledge of the theory of hyperbolic systems in one space dimension to compute numerical fluxes. It is at this point where one can use the theory of Riemann Invariant Manifolds to find the states that are connected with an equivalent 1-D characteristic problem.

The conventional way of extending these 1-D schemes to more space dimensions is through Strang-type, dimensional splitting, given in Strang (1968). Each spatial dimension is treated separately, and the result is the "sum" of one-dimensional problems in the grid directions. Unsplit schemes like that of Colella (1990) use the grid direction to set up a 1-D problem, but the states used as the initial condition for the Riemann problem are not clearly related via a 1-D problem, even though they are corrected for multidimensional effects. Efforts to create a genuinely multidimensional scheme are those by Roe (1986); Hirsch & Lacor (1989), and Deconinck *et al.* (1986). It is also easy to extend the Taylor-series expansion method, mentioned earlier, to multidimensional flows. The states computed in that way are not clearly related via the 1-D characteristic equations, but the resulting scheme works in practice. Moreover, this scheme is used as a reference point for the multidimensional schemes that are proposed, using the RIM wave decomposition.

Consider now the case of two-dimensional flow of a perfect gas. The second-order Godunov scheme will be described and used as the starting point for the proposed multidimensional corrections. The local geometry of a 2-D computational cell is shown in Fig. 3. An orthogonal grid in the x and y -directions is used. As will be seen later, this restriction on the grid can be dropped when the multidimensional corrections are introduced.

The equations of motion for the two-dimensional case are

$$\frac{\partial U}{\partial t} + \frac{\partial F_x(U)}{\partial x} + \frac{\partial F_y(U)}{\partial y} = 0, \quad (21)$$

where

$$U = \begin{pmatrix} \rho \\ \rho u \\ \rho v \\ \rho e_t \end{pmatrix}, \quad F_x(U) = \begin{pmatrix} \rho u \\ p + \rho u^2 \\ \rho uv \\ \rho ue_t + pu \end{pmatrix}, \quad F_y(U) = \begin{pmatrix} \rho v \\ \rho uv \\ p + \rho v^2 \\ \rho ve_t + pv \end{pmatrix}. \quad (22)$$

FIG.3 The geometry of the 2-D computational cell (i, j) . The interface between the cells (i, j) and $(i+1, j)$ is denoted by $(i+1/2, j)$. N_s is the unit vector normal to this interface. For an orthogonal grid this corresponds to the unit vector in the x -direction.

$\mathbf{u} = (u, v)^T$ is the two-dimensional, velocity vector, and $e_t = e + \frac{1}{2}|\mathbf{u}|^2$ is the total energy. The internal energy e is related to the pressure p by the perfect gas equation of state (3).

The spatial-interpolation scheme is the one-dimensional scheme given by Eqs. (7)–(10) and is implemented in the two orthogonal grid directions. As mentioned earlier, the spatial-interpolation scheme is a very important step, but is independent of the efforts to correct for multidimensional effects in the time integration. One can devise higher-order interpolation schemes, which take into account the presence of discontinuities, such as the interpolation used in ENO schemes. See Harten *et al.* (1987). It is also possible to devise schemes that work on unstructured grids. At any given time, knowledge of the spatial gradients of the flow will be assumed in using the theory of Riemann Invariant Manifolds to develop a multidimensional scheme.

A Riemann problem is solved at each interface to determine the states at the time level $t_n + \Delta t$. The two states that are used as the initial condition for the Riemann problem at the interface $(i + 1/2, j)$ are given by the Taylor series expansions on either side of the interface. The left state is given by expanding about the center of the $(i, j)^{\text{th}}$ cell to the center of the interface, \mathbf{x}_p , at the later time $t + \Delta t$. It is easy to see that the extension of Eq. (19) to the two-dimensional case is

$$U_L = U_{ij} + [(\mathbf{x}_p - \mathbf{x}_c)I - \Delta t \mathbf{A}] \cdot \nabla U, \quad (23)$$

where \mathbf{x}_c is the center of the cell, I is the unit matrix and

$$\mathbf{A} \equiv (A_x, A_y)^T = \left(\frac{\partial F_x(U)}{\partial U}, \frac{\partial F_y(U)}{\partial U} \right)^T. \quad (24)$$

It is more convenient to expand the primitive variables ρ , p and \mathbf{u} instead of the conserved vector U . The left state is, then, given by

$$\rho_L = \rho + [(\mathbf{x}_p - \mathbf{x}_c) - \mathbf{u}\Delta t] \cdot \nabla \rho - \Delta t \rho \nabla \cdot \mathbf{u}, \quad (25)$$

$$p_L = p + [(\mathbf{x}_p - \mathbf{x}_c) - \mathbf{u}\Delta t] \cdot \nabla p - \Delta t \rho a^2 \nabla \cdot \mathbf{u}, \quad (26)$$

$$\mathbf{u}_L = \mathbf{u} + [(\mathbf{x}_p - \mathbf{x}_c) - \mathbf{u}\Delta t] \cdot \nabla \mathbf{u} - \Delta t \frac{1}{\rho} \nabla p, \quad (27)$$

where all quantities are evaluated at the center of the $(i, j)^{\text{th}}$ cell. Similarly, one can find the right state by Taylor expanding about the center of the $(i + 1, j)^{\text{th}}$ cell. The velocity component normal to the interface, *i.e.*, $\mathbf{u}_L \cdot \mathbf{N}_s$ is used as the left scalar velocity for the 1-D Riemann problem. In other words, a one-dimensional Riemann problem is solved in the direction of the grid line, using the above left and right states. As mentioned earlier, these states are not clearly related by the 1-D characteristic equations even in smooth, shock-free flow. The tangential velocity component used to compute the numerical fluxes at the interface, is $\mathbf{u}_L \cdot \mathbf{N}_s^\perp$ if $\mathbf{u}_L \cdot \mathbf{N}_s > 0$; otherwise it is $\mathbf{u}_R \cdot \mathbf{N}_s^\perp$. The notation

$$\mathbf{a}^\perp \equiv (\hat{\mathbf{e}}_x \times \hat{\mathbf{e}}_y) \times \mathbf{a}, \quad (28)$$

for an arbitrary, two-dimensional vector \mathbf{a} , will be used throughout. \mathbf{a}^\perp is just \mathbf{a} , rotated by 90° .

3. Multidimensional, Second-Order Godunov Scheme

From the theory of Riemann Invariant Manifolds it is seen that the original compressible Euler equations can be substituted by the following equivalent system

$$\begin{aligned}\frac{\partial R_n}{\partial t} + (\mathbf{u} + \mathcal{M}_n a \mathbf{N}) \cdot \nabla R_n &= 0 \\ \frac{\partial R_0}{\partial t} + \mathbf{u} \cdot \nabla R_0 &= 0,\end{aligned}\tag{29}$$

where

$$\begin{aligned}\mathcal{M}_n &= \frac{\mathbf{n} \cdot \nabla p + \rho a \nabla \cdot \mathbf{u}}{\left| \nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n} \right|}, \\ \mathbf{N} &= \frac{\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}}{\left| \nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n} \right|}.\end{aligned}$$

This is a decomposition into a set of scalar fields, which is different from the characteristic decomposition. From a computational point of view one can formally try to discretize these equations in a way that is consistent with a conservative discretization of the original equations, has a prescribed order of accuracy and does not create spurious oscillations in the presence of discontinuities.

In the following numerical application it is proposed to use the Riemann Invariant Manifolds that pass through the interface of each computational cell to find the states that are clearly related through an equivalent one-dimensional, characteristic problem. As a first step, the geometry of the Riemann Invariant Manifold $R_n = \text{const}$, corresponding to the arbitrary unit vector \mathbf{n} , will be examined in the vicinity of the computational cell (i, j) . The spatial gradients are assumed known from the spatial-interpolation scheme. Moreover, the spatial gradients are constant in each cell, since a linear interpolation is used. The unit normal \mathbf{N} and the algebraic normal Mach number \mathcal{M}_n of the 2-D front $R_n = \text{const}$ are given by

$$\mathbf{N} = \frac{\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}}{\left| \nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n} \right|},\tag{30}$$

$$\mathcal{M}_n \equiv \frac{\mathbf{n} \cdot \nabla p + \rho a \nabla \cdot \mathbf{u}}{\left| \nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n} \right|}.\tag{31}$$

Both quantities are assumed constant in each computational cell. An arbitrary direction on the manifold $R_n = \text{const}$ is given by

$$\dot{\mathbf{x}}_n(t) = \mathbf{u} + a\boldsymbol{\nu}, \quad (32)$$

where

$$\boldsymbol{\nu} \equiv \mathcal{M}_n \mathbf{N} + \mathcal{M}_t \mathbf{N}^\perp. \quad (33)$$

\mathcal{M}_t is unspecified and it reflects the infinity of paths on this particular manifold. The Mach number of a particular trajectory $\dot{\mathbf{x}}_n(t)$ is

$$\mathcal{M} \equiv |\boldsymbol{\nu}| = \sqrt{\mathcal{M}_n^2 + \mathcal{M}_t^2} > 0. \quad (34)$$

This positive number \mathcal{M} contains the information about the relative position of the corresponding trajectory and the bicharacteristic conoid. When $\mathcal{M} = 1$, the path is tangent to the bicharacteristic cone. When $\mathcal{M} < 1$, it is time-like and when $\mathcal{M} > 1$, it is space-like.

The solution is known at time t . From the knowledge of the spatial gradients of the flow it is possible to find, approximately, all paths on the manifold $R_n = \text{const}$, which pass through the center of the interface $(i + 1/2, j)$ at time $t + \Delta t$. These paths must be such that

$$\mathbf{x}_p = \mathbf{x}_n(t + \Delta t) = \mathbf{x}_n(t) + \int_t^{t+\Delta t} [\mathbf{u}(\tau, \mathbf{x}_n(\tau)) + a(\tau, \mathbf{x}_n(\tau))\boldsymbol{\nu}(\tau, \mathbf{x}_n(\tau))] d\tau. \quad (35)$$

By approximating these paths by straight lines in time, one finds

$$\mathbf{x}_p \approx \mathbf{x}_w + \Delta t [\mathbf{u}(t, \mathbf{x}_w) + a(t, \mathbf{x}_w)\boldsymbol{\nu}(t, \mathbf{x}_w)], \quad (36)$$

where $\mathbf{x}_w \equiv \mathbf{x}_n(t)$. Using the linear interpolants for the velocity \mathbf{u} and the speed of sound a at time t and the fact that $\boldsymbol{\nu}$ is constant in each cell,

$$\mathbf{x}_p - \mathbf{x}_w \approx \Delta t \{ \mathbf{u} + (\mathbf{x}_w - \mathbf{x}_c) \cdot \nabla \mathbf{u} + [a + (\mathbf{x}_w - \mathbf{x}_c) \cdot \nabla a] \boldsymbol{\nu} \}, \quad (37)$$

where all quantities are now evaluated at the center of the cell. Eq. (37) can be used to solve for \mathbf{x}_w as a function of \mathcal{M}_t . It can be written as

$$[I + \Delta t (\nabla \mathbf{u} + \boldsymbol{\nu} \nabla a)] (\mathbf{x}_w - \mathbf{x}_c) \approx \mathbf{x}_p - \mathbf{x}_c - \Delta t (\mathbf{u} + a\boldsymbol{\nu}). \quad (38)$$

Eq. (38) is a linear system in the unknown vector $\mathbf{x}_w - \mathbf{x}_c$. The determinant of this system is easily found to be

$$\begin{aligned} D &= 1 + \Delta t (\nabla \cdot \mathbf{u}) + \Delta t^2 \det(\nabla \mathbf{u}) + \Delta t \boldsymbol{\nu} \cdot \left[I + \Delta t (\widehat{\nabla \mathbf{u}}) \right] \nabla a \\ &= 1 + \Delta t (\nabla \cdot \mathbf{u} + \boldsymbol{\nu} \cdot \nabla a) + \Delta t^2 \left[\det(\nabla \mathbf{u}) + \boldsymbol{\nu} \cdot (\widehat{\nabla \mathbf{u}}) \nabla a \right]. \end{aligned} \quad (39)$$

For small enough timestep Δt , $D \approx 1$. Eq. (38) can be solved to give

$$\mathbf{x}_p - \mathbf{x}_w = (1 - 1/D) \Delta \mathbf{x}_p + \frac{\Delta t}{D} \left[\mathbf{u} - (\widehat{\nabla \mathbf{u}}) (\Delta \mathbf{x}_p - \Delta t \mathbf{u}) \right] + \frac{\Delta t}{D} a \hat{T} \boldsymbol{\nu}, \quad (40)$$

where $\Delta \mathbf{x}_p \equiv \mathbf{x}_p - \mathbf{x}_c$, $a \hat{T}$ is the tensor

$$a \hat{T} \equiv a I + (\nabla a)^\perp (\Delta \mathbf{x}_p)^\perp + \Delta t \left[a (\widehat{\nabla \mathbf{u}}) - (\nabla a)^\perp \mathbf{u}^\perp \right], \quad (41)$$

and

$$(\widehat{\nabla \mathbf{u}}) \equiv \begin{pmatrix} \frac{\partial v}{\partial y} & \frac{\partial v}{\partial x} \\ \frac{\partial u}{\partial y} & \frac{\partial u}{\partial x} \end{pmatrix}, \quad (\widetilde{\nabla \mathbf{u}}) \equiv \begin{pmatrix} \frac{\partial v}{\partial y} & -\frac{\partial u}{\partial y} \\ -\frac{\partial v}{\partial x} & \frac{\partial u}{\partial x} \end{pmatrix}. \quad (42)$$

Eq. (40) gives \mathbf{x}_w as a function of \mathcal{M}_t , which is contained in $\boldsymbol{\nu}$. In other words, it is the locus of all points, at time t , that are connected with point $(t + \Delta t, \mathbf{x}_p)$ by the 1-D characteristic differential equation

$$\frac{dp}{dt} + \rho a \frac{du_n}{dt} = 0, \quad (43)$$

where $u_n = \mathbf{u} \cdot \mathbf{n}$, for the particular choice of \mathbf{n} .

For the point \mathbf{x}_w to be inside the cell (i, j) , the following relations must hold

$$\begin{aligned} 0 &< (\mathbf{x}_p - \mathbf{x}_w) \cdot \mathbf{N}_s < \Delta x \\ |(\mathbf{x}_p - \mathbf{x}_w) \cdot \mathbf{N}_s^\perp| &< 0.5 \Delta y, \end{aligned} \quad (44)$$

where $(\Delta x, \Delta y)$ is the size of the cell. If the point \mathbf{x}_w is restricted to the half of the cell closest to the interface $(i + 1/2, j)$, then

$$\begin{aligned} 0 &< (\mathbf{x}_p - \mathbf{x}_w) \cdot \mathbf{N}_s < 0.5 \Delta x \\ |(\mathbf{x}_p - \mathbf{x}_w) \cdot \mathbf{N}_s^\perp| &< 0.5 \Delta y, \end{aligned} \quad (45)$$

FIG.4 The locus of all points x_w in the cell (i,j) at time t , which are connected with point $(t + \Delta t, x_p)$ by the 1-D characteristic differential Equation (43).

Eq. (40) can be used to find the range of the parameter \mathcal{M}_t for which the inequalities (44) or (45) hold. This range can be found explicitly if the simplifying assumption $D \approx 1$ is made. In that case, Eq. (40) becomes

$$\frac{x_p - x_w}{\Delta t} \approx V_c + a\hat{T}\nu, \quad (46)$$

where

$$V_c \equiv \mathbf{u} - (\widetilde{\nabla \mathbf{u}})(\Delta \mathbf{x}_p - \Delta t \mathbf{u}). \quad (47)$$

The inequalities (45) can now be written

$$\begin{aligned} 0 < u_s < 0.5 \frac{\Delta x}{\Delta t} &\equiv 0.5 u_g \\ |v_s| < 0.5 \frac{\Delta y}{\Delta t} &\equiv 0.5 v_g, \end{aligned} \quad (48)$$

where

$$\begin{aligned} u_s &\equiv \frac{x_p - x_w}{\Delta t} \cdot \mathbf{N}_s = \mathbf{V}_c \cdot \mathbf{N}_s + a\nu \cdot (\hat{T}^T \mathbf{N}_s) \\ v_s &\equiv \frac{x_p - x_w}{\Delta t} \cdot \mathbf{N}_s^\perp = \mathbf{V}_c \cdot \mathbf{N}_s^\perp + a\nu \cdot (\hat{T}^T \mathbf{N}_s^\perp). \end{aligned} \quad (49)$$

Using Eq. (33), the inequalities (48) become

$$\begin{aligned} 0 < \mathbf{V}_c \cdot \mathbf{N}_s + a\mathcal{M}_n \mathbf{N} \cdot \mathbf{k}_s - a\mathcal{M}_t \mathbf{N} \cdot \mathbf{k}_s^\perp < 0.5u_g \\ -0.5v_g < \mathbf{V}_c \cdot \mathbf{N}_s^\perp + a\mathcal{M}_n \mathbf{N} \cdot \boldsymbol{\kappa}_s - a\mathcal{M}_t \mathbf{N} \cdot \boldsymbol{\kappa}_s^\perp < 0.5v_g, \end{aligned} \quad (50)$$

where

$$\mathbf{k}_s \equiv \hat{T}^T \mathbf{N}_s, \quad \boldsymbol{\kappa}_s \equiv \hat{T}^T \mathbf{N}_s^\perp. \quad (51)$$

This can be written as

$$\begin{aligned} \mathbf{V}_c \cdot \mathbf{N}_s + a\mathcal{M}_n \mathbf{N} \cdot \mathbf{k}_s - 0.5u_g < a\mathcal{M}_t \mathbf{N} \cdot \mathbf{k}_s^\perp < \mathbf{V}_c \cdot \mathbf{N}_s + a\mathcal{M}_n \mathbf{N} \cdot \mathbf{k}_s \\ \mathbf{V}_c \cdot \mathbf{N}_s^\perp + a\mathcal{M}_n \mathbf{N} \cdot \boldsymbol{\kappa}_s - 0.5v_g < a\mathcal{M}_t \mathbf{N} \cdot \boldsymbol{\kappa}_s^\perp < \mathbf{V}_c \cdot \mathbf{N}_s^\perp + a\mathcal{M}_n \mathbf{N} \cdot \boldsymbol{\kappa}_s + 0.5v_g. \end{aligned} \quad (52)$$

This is equivalent to

$$\mathcal{M}_t \in (\alpha_-, \alpha_+) \cap (\beta_-, \beta_+), \quad (53)$$

where

$$\begin{aligned} \alpha_\pm &\equiv \max_{\min} \left(\frac{\mathbf{V}_c \cdot \mathbf{N}_s + a\mathcal{M}_n \mathbf{N} \cdot \mathbf{k}_s - 0.5u_g}{a\mathbf{N} \cdot \mathbf{k}_s^\perp}, \frac{\mathbf{V}_c \cdot \mathbf{N}_s + a\mathcal{M}_n \mathbf{N} \cdot \mathbf{k}_s}{a\mathbf{N} \cdot \mathbf{k}_s^\perp} \right) \\ \beta_\pm &\equiv \max_{\min} \left(\frac{\mathbf{V}_c \cdot \mathbf{N}_s^\perp + a\mathcal{M}_n \mathbf{N} \cdot \boldsymbol{\kappa}_s - 0.5v_g}{a\mathbf{N} \cdot \boldsymbol{\kappa}_s^\perp}, \frac{\mathbf{V}_c \cdot \mathbf{N}_s^\perp + a\mathcal{M}_n \mathbf{N} \cdot \boldsymbol{\kappa}_s + 0.5v_g}{a\mathbf{N} \cdot \boldsymbol{\kappa}_s^\perp} \right). \end{aligned} \quad (54)$$

Define

$$\mathcal{M}_t^\pm \equiv \min_{\max} (\alpha_\pm, \beta_\pm). \quad (55)$$

If $\mathcal{M}_t^- > \mathcal{M}_t^+$, then there is no solution to these inequalities. Otherwise, the inequalities are satisfied for

$$\mathcal{M}_t \in (\mathcal{M}_t^-, \mathcal{M}_t^+). \quad (56)$$

This range of values can be restricted further, if one requires that

$$\mathcal{M} = \sqrt{\mathcal{M}_n^2 + \mathcal{M}_t^2} \leq \mathcal{M}_{\max}. \quad (57)$$

This restricts the locus of points to those within a certain distance from the domain of dependence of the point $(t + \Delta t, \mathbf{x}_p)$.

It is now a straightforward calculation to find the pressure, density and velocity at the point \mathbf{x}_w , using the linear interpolants in the $(i, j)^{\text{th}}$ cell. We denote this state with the superscript W . The pressure at point (t, \mathbf{x}_w) is given by

$$p^W = p + (\mathbf{x}_w - \mathbf{x}_c) \cdot \nabla p. \quad (58)$$

By substituting \mathbf{x}_w from Eq. (40), one finds

$$\begin{aligned} p^W = p^G &- a [\boldsymbol{\nu} \cdot \nabla p - \rho a \nabla \cdot \mathbf{u}] \Delta t - (1 - 1/D) \Delta \mathbf{x}_p \cdot \nabla p \\ &- \Delta t [\mathbf{E}_\nu^{(1)} - (1 - 1/D) (\mathbf{u} + a\boldsymbol{\nu})] \cdot \nabla p - \Delta t^2 \mathbf{E}_\nu^{(2)} \cdot \nabla p, \end{aligned} \quad (59)$$

where p^G is the pressure given by the conventional Godunov scheme in Eq. (26); *i.e.*,

$$p^G = p + [(\mathbf{x}_p - \mathbf{x}_c) - \Delta t \mathbf{u}] \cdot \nabla p - \Delta t \rho a^2 \nabla \cdot \mathbf{u}. \quad (60)$$

All quantities are evaluated at the center of the cell, and the two vectors $\mathbf{E}_\nu^{(1)}$ and $\mathbf{E}_\nu^{(2)}$ are given by

$$\mathbf{E}_\nu^{(1)} \equiv \frac{1}{D} \left[(\boldsymbol{\nu} \cdot \Delta \mathbf{x}_p^\perp) (\nabla a)^\perp - (\widetilde{\nabla \mathbf{u}}) \Delta \mathbf{x}_p \right], \quad (61)$$

$$\mathbf{E}_\nu^{(2)} \equiv \frac{1}{D} \left[(\widetilde{\nabla \mathbf{u}}) (\mathbf{u} + a\boldsymbol{\nu}) - (\boldsymbol{\nu} \cdot \mathbf{u}^\perp) (\nabla a)^\perp \right]. \quad (62)$$

Similarly, for the component of the velocity vector in the \mathbf{n} direction, one can show that

$$\begin{aligned} \mathbf{u}^W \cdot \mathbf{n} = \mathbf{u}^G \cdot \mathbf{n} &+ \left[\frac{1}{\rho} \mathbf{n} \cdot \nabla p - a\boldsymbol{\nu} \cdot (\nabla \mathbf{u})^T \mathbf{n} \right] - (1 - 1/D) \Delta \mathbf{x}_p \cdot (\nabla \mathbf{u})^T \mathbf{n} \\ &- \Delta t [\mathbf{E}_\nu^{(1)} - (1 - 1/D) (\mathbf{u} + a\boldsymbol{\nu})] \cdot (\nabla \mathbf{u})^T \mathbf{n} - \Delta t^2 \mathbf{E}_\nu^{(2)} \cdot (\nabla \mathbf{u})^T \mathbf{n}. \end{aligned} \quad (63)$$

By the definition of the Riemann Invariant Manifold,

$$\boldsymbol{\nu} \cdot [\nabla p + \rho a (\nabla \mathbf{u})^T \mathbf{n}] = \mathbf{n} \cdot \nabla p + \rho a \nabla \cdot \mathbf{u}. \quad (64)$$

Therefore, Eq. (63) can be written

$$\begin{aligned} \mathbf{u}^W \cdot \mathbf{n} = \mathbf{u}^G \cdot \mathbf{n} &+ \frac{1}{\rho} [\boldsymbol{\nu} \cdot \nabla p - \rho a \nabla \cdot \mathbf{u}] \Delta t - (1 - 1/D) \Delta \mathbf{x}_p \cdot (\nabla \mathbf{u})^T \mathbf{n} \\ &- \Delta t [\mathbf{E}_\nu^{(1)} - (1 - 1/D) (\mathbf{u} + a\boldsymbol{\nu})] \cdot (\nabla \mathbf{u})^T \mathbf{n} - \Delta t^2 \mathbf{E}_\nu^{(2)} \cdot (\nabla \mathbf{u})^T \mathbf{n}. \end{aligned} \quad (65)$$

It is seen from these equations that the leading order difference between the state given by the Godunov scheme and the state given by the Riemann Invariant Manifold is the term

$$\boldsymbol{\nu} \cdot \nabla p - \rho a \nabla \cdot \mathbf{u} , \quad (66)$$

for both the pressure and the velocity. The density is given by a similar equation,

$$\begin{aligned} \rho^w = \rho^G &- [a \boldsymbol{\nu} \cdot \nabla \rho - \rho \nabla \cdot \mathbf{u}] \Delta t - (1 - 1/D) \Delta \mathbf{x}_p \cdot \nabla \rho \\ &- \Delta t [\mathbf{E}_\nu^{(1)} - (1 - 1/D)(\mathbf{u} + a \boldsymbol{\nu})] \cdot \nabla \rho - \Delta t^2 \mathbf{E}_\nu^{(2)} \cdot \nabla \rho . \end{aligned} \quad (67)$$

The state computed this way, *i.e.*, by tracing the Riemann Invariant Manifold $R_n = \text{const}$, serves as the left state for a 1-D characteristic problem. To find the right state, one needs to trace the $R_{-n} = \text{const}$ manifold, which corresponds to the unit vector $-\mathbf{n}$. A locus of points (t, \mathbf{x}_w) can be found, which are connected with the point $(t + \Delta t, \mathbf{x}_p)$ by

$$\frac{dp}{dt} - \rho a \frac{du_n}{dt} = 0 . \quad (68)$$

These points may lie in the $(i, j)^{\text{th}}$ cell or the $(i + 1, j)^{\text{th}}$ cell or both, depending on the local flow gradients. The solution to this 1-D characteristic problem will give the pressure and velocity component $\mathbf{u} \cdot \mathbf{n}$ at the point $(t + \Delta t, \mathbf{x}_p)$.

The density is found by tracing the streamline back in time in a way completely analogous to the way the Riemann Invariant paths were traced. The density is computed using Eqs. (17) and (18) as in the 1-D algorithm. This is because the states along the streamline are connected with the 1-D characteristic equation (16) even in the general multidimensional case.

It is obvious that the velocity component $\mathbf{u} \cdot \mathbf{n}^\perp$ is also needed. There are two ways to find this. One way is to examine the geometry of the Riemann Invariant Manifolds that correspond to the unit vectors $\pm \mathbf{n}^\perp$ and to set up another 1-D characteristic problem. There is a different way of calculating the velocity component $\mathbf{u} \cdot \mathbf{n}^\perp$, which is now described. The momentum equation is

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} + \frac{1}{\rho} \nabla p = 0 . \quad (69)$$

By taking the inner product of this equation with the constant unit vector \mathbf{n}^\perp , one finds

$$\frac{\partial}{\partial t} (\mathbf{u} \cdot \mathbf{n}^\perp) + \mathbf{u} \cdot (\nabla \mathbf{u})^T \mathbf{n}^\perp + \frac{1}{\rho} \mathbf{n}^\perp \cdot \nabla p = 0. \quad (70)$$

It can be seen that along any path $\dot{\mathbf{x}}(t) = \mathbf{u} + a\boldsymbol{\nu}_u$ in spacetime such that

$$\boldsymbol{\nu}_u \cdot (\nabla \mathbf{u})^T \mathbf{n}^\perp = \frac{1}{\rho a} \mathbf{n}^\perp \cdot \nabla p, \quad (71)$$

one has

$$\frac{\partial}{\partial t} (\mathbf{u} \cdot \mathbf{n}^\perp) + (\mathbf{u} + a\boldsymbol{\nu}_u) \cdot \nabla (\mathbf{u} \cdot \mathbf{n}^\perp) = 0, \quad (72)$$

which means that the velocity component $\mathbf{u} \cdot \mathbf{n}^\perp$ is constant along this path. In effect, a manifold is defined in a way completely analogous to the Riemann Invariant Manifolds. It is straightforward to show that Eq. (71) implies that

$$\boldsymbol{\nu}_u = \zeta_n \mathbf{N}_u + \zeta_t \mathbf{N}_u^\perp, \quad (73)$$

where

$$\mathbf{N}_u = \frac{(\nabla \mathbf{u})^T \mathbf{n}^\perp}{|(\nabla \mathbf{u})^T \mathbf{n}^\perp|}, \quad (74)$$

$$\zeta_n = \frac{1}{\rho a} \frac{\mathbf{n}^\perp \cdot \nabla p}{|(\nabla \mathbf{u})^T \mathbf{n}^\perp|}. \quad (75)$$

The equations for this manifold are the same as those for the Riemann Invariant Manifolds with the following substitutions,

$$\mathbf{N} \rightarrow \mathbf{N}_u, \quad \mathcal{M}_n \rightarrow \zeta_n \quad \text{and} \quad \mathcal{M}_t \rightarrow \zeta_t. \quad (76)$$

One can find a locus of points in a given cell by tracing this manifold back in time, exactly the way the Riemann Invariant Manifolds were traced. It can be seen, then, that the velocity component $\mathbf{u} \cdot \mathbf{n}^\perp$ is given by

$$\begin{aligned} \mathbf{u}^w \cdot \mathbf{n}^\perp &= \mathbf{u}^G \cdot \mathbf{n}^\perp - (1 - 1/D_u) \Delta \mathbf{x}_p \cdot (\nabla \mathbf{u})^T \mathbf{n}^\perp - \Delta t^2 \mathbf{E}_{\nu_u}^{(2)} \cdot (\nabla \mathbf{u})^T \mathbf{n}^\perp \\ &\quad - \Delta t [\mathbf{E}_{\nu_u}^{(1)} - (1 - 1/D_u) (\mathbf{u} + a\boldsymbol{\nu}_u)] \cdot (\nabla \mathbf{u})^T \mathbf{n}^\perp, \end{aligned} \quad (77)$$

where

$$D_u \equiv 1 + \Delta t (\nabla \cdot \mathbf{u} + \boldsymbol{\nu}_u \cdot \nabla a) + \Delta t^2 \left[\det(\nabla \mathbf{u}) + \boldsymbol{\nu}_u \cdot (\widehat{\nabla \mathbf{u}}) \nabla a \right], \quad (78)$$

$$\mathbf{E}_{\nu_u}^{(1)} \equiv \frac{1}{D_u} \left[(\nu_u \cdot \Delta \mathbf{x}_p^\perp) (\nabla a)^\perp - (\widetilde{\nabla \mathbf{u}}) \Delta \mathbf{x}_p \right], \quad (79)$$

$$\mathbf{E}_{\nu_u}^{(2)} \equiv \frac{1}{D_u} \left[(\widetilde{\nabla \mathbf{u}}) (\mathbf{u} + a \nu_u) - (\nu_u \cdot \mathbf{u}^\perp) (\nabla a)^\perp \right]. \quad (80)$$

The theory of Riemann Invariant Manifolds has given us a way of finding a 1-D characteristic problem near the interface $(i + 1/2, j)$. The solution of the 1-D problem gives us the state at $(t + \Delta t, \mathbf{x}_p)$ and hence the numerical fluxes. In the procedure described, the unit vector \mathbf{n} was arbitrary. Therefore, the derived equations give us a two-parameter family of schemes for computing the fluxes. One degree of freedom comes from \mathbf{n} and the other from the freedom to choose \mathcal{M}_t , although the latter is restricted by relations like (56). This family of schemes is consistent with the multidimensional theory and provides a way for correcting the conventional Godunov scheme. The conventional scheme assumes $\mathbf{n} = \mathbf{N}_s$; *i.e.*, it sets up a 1-D problem in the grid direction. If this choice is made, then one is left with choosing \mathcal{M}_t in each case. The conventional scheme based on the Taylor series extrapolation always takes the left state from the cell (i, j) and the right state from the cell $(i + 1, j)$. The proposed, multidimensional scheme examines the geometry of the manifolds $R_n = \text{const}$ and $R_{-n} = \text{const}$ to determine the left and right states. It was seen in Eqs. (55) and (56) that $\mathcal{M}_t^- < \mathcal{M}_t^+$ must hold if the $(i, j)^{\text{th}}$ cell can be used to compute the left state. It is possible for both states to be taken from one cell, depending on the local flow gradients. A possible choice for \mathcal{M}_t , which works well in practice, is

$$\mathcal{M}_t = (\mathcal{M}_t^- + \mathcal{M}_t^+)/2. \quad (81)$$

So far, the tacit assumption of smooth, shock-free flow was made. The theory of Riemann Invariant Manifolds has been developed with the assumption that the flow gradients exist and are smooth. It is known that in gas-dynamical flows, discontinuities in the flow variables and their gradients may be present. The theory, nevertheless, can still be used for flows with such discontinuities. In the 1-D case, although the characteristics cannot propagate information across shocks, they can still be used on either side of shocks to determine the states that are related via the jump conditions. It is the generalization of the 1-D characteristic equations

that leads to the concept of the Riemann problem. In the context of a Godunov scheme, discontinuities are assumed at every cell interface. In the smooth regions of the flow, these discontinuities are infinitesimally weak, and the characteristics are used to compute the numerical fluxes as shown in Fig. 2. To take care of the flow regions containing shocks, the characteristic problem is generalized to the Riemann problem. In effect, the characteristic equations are discretized to second-order accuracy where the flow is smooth and in a way which is consistent with the appropriate jump conditions when discontinuities are present.

In the multidimensional case the situation is similar. The Riemann Invariant Manifolds cannot propagate information through shocks or characteristic surfaces that contain derivative discontinuities. Nevertheless, they can be used on either side of these discontinuities to determine the states that are connected with the appropriate jump conditions. The easiest way of implementing this, although possibly not the most accurate, is to use the left and right states, determined by the Riemann Invariant Manifolds, as the initial condition for a 1-D Riemann problem. Care must be taken so that the discretization of the equations is consistent with the jump conditions when shocks are present. This geometric picture also suggests the possibility of changing the unit vector \mathbf{n} locally, so that it coincides with the unit normal of the discontinuity fronts. For example, consider a shock with unit normal \mathbf{n} , locally. The Riemann Invariant Manifolds $R_{\pm\mathbf{n}} = \text{const}$ on either side of the shock can be used to determine the states that are related with the jump conditions.

This procedure is reminiscent of the attempts to fit shocks in flows when the method of characteristics is used. The analogy is not surprising, since the theory of Riemann Invariant Manifolds can be looked at as an extension of the method of characteristics to the general, multidimensional case.

It is also interesting to determine when the conventional MUSCL scheme, at least the version used here as a reference point, will give the same results as the multidimensional scheme. It is seen from Equations (59), (65), (77) and (67) that the two schemes will coincide to *leading order*, if the left state can be taken from

the left cell, the right state from the right cell and in addition,

$$\begin{aligned}\nu \cdot \nabla p - \rho a \nabla \cdot \mathbf{u} &= 0, \\ a \nu \cdot \nabla \rho - \rho \nabla \cdot \mathbf{u} &= 0,\end{aligned}\tag{82}$$

for both manifolds $R_{\pm n} = \text{const.}$ This cannot always be satisfied, but it now becomes clear why the conventional schemes give reasonable results in multidimensional flows. The terms in Eq. (82) can be taken to be very small and sometimes zero. This depends on the local flow conditions.

It should be noted here that the scheme based on the RIM decomposition is not meant to be the ultimate second-order multidimensional scheme that is better than all other schemes including the dimensionally split ones. The first author strongly believes that no such scheme exists. It turns out to be a very robust scheme without stability problems and it differs from most characteristic based schemes in the special directions which are used to calculate the numerical fluxes. This difference may become important in some parts of the flow.

4. Numerical Applications

The new multidimensional Godunov scheme developed in the previous section, is used to compute two gas-dynamical flows on rectangular grids. The first case is the steady-state, regular shock reflection off a wall at low resolution. The second flow is a double Mach reflection of a planar-shock incident on an oblique surface. These two problems have been used extensively as test cases for a variety of numerical methods, and there are detailed comparisons of existing methods in the literature; *e.g.*, see Woodward and Colella (1984) and Colella (1990). In all the calculations, a perfect gas is assumed, with constant, specific heat ratio equal to $\gamma = 1.4$.

FIG.5 Regular shock reflection. Pressure contour levels at time $t = 5$. There are 30 contour levels in the range $0.5 < p < 3.5$. The resolution is 60×20 cells.

4.1 Regular shock reflection

This case is a simple shock reflection, which has been used as a test case by many investigators. Colella (1990), among others, describes the initial and boundary conditions for this problem.

The computational domain is the rectangular domain $0 < x < 4$ and $0 < y < 1$. The lower boundary $y = 0$ is a reflecting wall, and at the right boundary $x = 4$, outflow conditions are imposed. The following inflow conditions are specified at the left boundary $x = 0$,

$$p = 1.0/1.4 \quad \rho = 1.0 \quad u = 2.9 \quad v = 0, \quad (83)$$

and at the top boundary $y = 1$, the following Dirichlet boundary condition is imposed:

$$p = 1.52819 \quad \rho = 1.69997 \quad u = 2.61934 \quad v = -0.50632. \quad (84)$$

The initial condition in the entire domain is that of the inflow condition.

The computation is carried out with a CFL number of 0.40 until a steady state is achieved. Pressure contours at time $t = 5$ are shown in Fig. 5. The pressure profile at the location $y = 0.525$ is shown in Fig. 6. Some oscillations can be seen in the postshock region. The present scheme employs no explicit, artificial dissipation as does the PPM scheme described by Colella and Woodward (1984). According to these authors this additional dissipation is needed to suppress oscillations behind shocks that don't move with respect to the grid.

FIG.6 Regular shock reflection at time $t = 5$. Pressure profile along the line $y = 0.525$.

4.2 Double Mach reflection

This flow has been used by Woodward and Colella (1984) as a test problem for the comparison of existing numerical methods. The initial condition is that of a strong planar-shock incident on an oblique surface at a 30° angle. The shock Mach number is $M_s = 10$. The computational domain is the rectangular domain $0 < x < 4$ and $0 < y < 1$. The incident shock at time $t = 0$ is an oblique shock starting at the location $(x, y) = (1/6, 0)$ and forming a 60° angle with the positive x -axis. The lower boundary is a reflecting wall for $1/6 < x < 4$. At the small portion $0 < x < 1/6$ of the lower wall, a Dirichlet boundary condition is imposed, which corresponds to the initial post-shock flow. This artificial boundary condition ensures that the reflected shock is always attached to the point $(x, y) = (1/6, 0)$. The right boundary $x = 4$ is an outflow boundary, and the left boundary $x = 0$ is an inflow boundary with inflow conditions those of the initial post-shock flow. The

conditions at the top boundary $y = 1$ are specified to be those corresponding to the motion of the initial planar shock wave.

Results of this unsteady calculation are shown at time $t = 0.20$. The solution is shown in Figs. 7, for a low-resolution computation corresponding to a 120×30 grid. In Figs. 8, the higher-resolution computation is shown. This corresponds to a 240×60 grid.

FIG.7a Double Mach reflection. Density contour levels at time $t = 0.20$. There are 30 contour levels in the range $1.7 < \rho < 18.5$. The resolution is 120×30 cells.

FIG.7b Double Mach reflection. Density contour levels at time $t = 0.20$. There are 30 contour levels in the range $1.73 < u < 21.0$. The resolution is 240×60 cells.

FIG.8a Double Mach reflection. Pressure contour levels at time $t = 0.20$. There are 30 contour levels in the range $2 < \rho < 450$. The resolution is 120×30 cells.

FIG.8b Double Mach reflection. Pressure contour levels at time $t = 0.20$. There are 30 contour levels in the range $2 < u < 480$. The resolution is 240×60 cells.

5. Conclusions

A new way of looking at multidimensional gas dynamics has been presented. Examining the local geometry of the Riemann Invariant Manifolds it is possible to develop effective, numerical methods for computing such flows. The theory allows one to develop numerical schemes that take into account the multidimensional character of these flows in a mathematically consistent way. This theory can be considered an extension of the method of characteristics to multidimensional flows. Although the theory was developed for smooth flows, it is possible to use the geometrical information of these manifolds to determine the appropriate 1-D problem

that needs to be solved across a flow discontinuity.

There are many ways of implementing these ideas numerically. As an example, it was shown how a second-order Godunov scheme can be modified to give a conservative, multidimensional, shock-capturing scheme for two-dimensional flows. The results from this scheme appear to be very close to those of conventional schemes, but a detailed study is needed. A more detailed study of the scheme and comparison with other conventional schemes is currently under way.
